Illness descriptions from outbreaks thought to be associated with coronaviruses have included the occurrence of vomiting and diarrhea of short duration, often accompanied by fever.<sup>117,130</sup> Besides gastroenteritis, HECVs have been reported in association with other gastrointestinal diseases including necrotizing enterocolitis,<sup>132,133</sup> and neonatal diarrhea<sup>122</sup> in infants, and tropical sprue.<sup>118,134</sup> In several reports of clinical signs and symptoms associated with the new severe acute respiratory syndrome (SARS)-associated coronavirus, diarrhea has been a common symptom, reported in around a quarter of patients.<sup>135,136</sup> It is not clear whether patients with the SARS coronavirus can have diarrhea without respiratory symptoms.

HECVs may be identified with EM by their distinctive 20-nm, clublike projections.<sup>137</sup> Enteric coronaviruses are distinct from respiratory coronaviruses and do not cross-react by enzyme-linked immunosorbent assay (ELISA) or immunoblots, although there is cross-reactivity on IEM.<sup>129</sup>

### TOROVIRUSES

Toroviruses are members of the family Coronaviridae and the genus *Torovirus*. They are pleomorphic, 100- to 150-nm, ssRNA viruses with 20-nm, clublike projections extending from the capsid.<sup>138–140</sup>

The epidemiology of these infections remains unclear. Toroviruses have been detected in stools of children and adults with diarrhea in developed countries.<sup>49,140–142</sup> However, in these studies there was no epidemiologic association with illness, and the detections could not be confirmed using additional tests. In an EM survey of diarrhea among children in Toronto, torovirus-like particles were detected in 224 (8%) of 3800 stool specimens. The particles in some of these stools were later confirmed as torovirus by an ELISA incorporating bovine and human antibodies.<sup>143</sup>

A serum response to infection can be measured in infected cows, which develop IgM and IgG following gastrointestinal infection,<sup>144</sup> but no serum immune response has been reported in humans. Electron microscopists can identify torovirus-like particles in human specimens but cannot confirm the detection.<sup>145</sup> Several additional methods including ELISA,<sup>144,146</sup> cDNA probes for hybridization,<sup>142</sup> and RT-PCR<sup>143</sup> have been used successfully in animals and hold promise for detection of human disease.

### OTHER VIRUSES

A variety of other viruses have been implicated in gastroenteritis to some degree including parvoviruses, enteroviruses,

reoviruses, and pestiviruses, and have been reviewed in detail elsewhere. Parvoviruses, reoviruses, and pestiviruses may cause diarrhea in nonhumans, and there are reports of human cases of gastrointestinal illnesses.<sup>147–153</sup> However, the data are inconclusive, and they are not currently thought to be causes of gastroenteritis in humans.

# Viral Hepatitis

MARTIN TAGLE  
STANLEY M. LEMON  
EUGENE R. SCHIFF

## INTRODUCTION

Viral hepatitis is an important cause of morbidity and mortality worldwide, particularly in the tropics. It is caused by no fewer than five distinct viruses, each with unique molecular characteristics and replication cycles but sharing a common tropism for the liver and overlapping clinical patterns of disease. In most tropical areas, clinically apparent acute viral hepatitis is uncommon among local people, since infection is acquired early in life and most often is subclinical. On the other hand, sporadic cases are frequent among visitors, and outbreaks of the enterically transmitted viruses have occasionally been reported when food or water becomes contaminated with human feces.<sup>1</sup> The general characteristics of the different hepatitis viruses are shown in Table 64-1.

## Hepatitis A

Hepatitis A is endemic in most tropical and subtropical regions of the world but is seldom diagnosed, since most infections are anicteric and acquired during childhood.<sup>1</sup> Outbreaks of hepatitis were described in Europe in the 17th and 18th centuries.<sup>2</sup> Epidemiologic analysis that led to the differentiation between hepatitis A ("infectious hepatitis") and hepatitis B ("serum hepatitis") came from studies done among

troops during World War II.<sup>2,3</sup> The hepatitis A virus was isolated in cell culture for the first time in 1979.

## AGENT

Hepatitis A virus (HAV) belongs to the family Picornaviridae, which includes the enteroviruses and rhinoviruses. HAV is a nonenveloped, single-stranded RNA virus, measuring approximately 27 to 28 nm in diameter. The linear genome (Fig. 64-1) is of positive or mRNA polarity and has a poly(A) tail at its 3' end.<sup>4</sup> The virus genome serves as the RNA message for translation of virus-specific proteins, which begins immediately after penetration of the cell and uncoating and is not dependent on virus replication or RNA transcription. HAV is relatively heat-stable and is inactivated by autoclaving, ultraviolet radiation, formalin, and iodine. HAV is destroyed by boiling within 5 minutes, but steaming of shellfish may not be sufficient to destroy infectivity.<sup>5</sup>

## EPIDEMIOLOGY

HAV is found in high titers in stools of infected persons, and the principal mode of transmission is fecal-oral. Person-to-person contact with infected family members remains one of the most important mechanisms of HAV transmission. Food-borne or waterborne transmission is promoted by the high stability of the virion in the environment and can occur when food or water is contaminated with HAV and ingested by susceptible persons. Some of the vehicles involved in outbreaks of HAV include raw or partially cooked shellfish, milk, salad, and hamburgers. Recently, an outbreak of hepatitis A involving 555 persons was reported, associated with consumption of green onions at a restaurant in Pennsylvania.<sup>6</sup> There were three deaths due to fulminant hepatitis. Green onions and other selected produce items (e.g., strawberries) may be more vulnerable to contamination because plant surfaces are particularly complex or prone to adherence of viral or fecal particles.<sup>7</sup> In addition, such produce is frequently imported unprocessed into the United States from Mexico and other countries with high HAV endemicity.

HAV is highly endemic in less developed countries, where most persons acquire the infection in early childhood.<sup>2,8</sup>

**Table 64-1** Characteristics of the Hepatitis Viruses

	Hepatitis A (HAV)	Hepatitis B (HBV)	Hepatitis C (HCV)	Hepatitis D (HDV)	Hepatitis E (HEV)
Nucleic acid	RNA	DNA	RNA	RNA	RNA
Antigens (Ag)	HAV Ag	HBsAg, HBcAg, HBeAg	Core, E2, NS3	HDV Ag	HEV Ag
Antibodies	IgM anti-HAV IgG anti-HAV	Anti-HBs Anti-HBc Anti-HBe	Anti-HCV	IgM anti-HDV IgG anti-HDV	Anti-HEV
Mode of transmission	Fecal-oral	Percutaneous, sexual, vertical	Percutaneous, ?sexual, ?perinatal	Percutaneous, sexual	Fecal-oral
Risk of chronicity	No	Yes	Yes	Yes	No
Vaccine available	Yes	Yes	No	No	No
Incubation period (days)	15–60	30–160	15–180	21–160	15–60

Areas of high endemicity, where travelers are particularly susceptible to acquire the infection, include most of Africa, Asia, and Central and South America. In some parts of the world with lower endemicity, such as Eastern Europe, the former Soviet Union, and parts of Asia, children may escape infection during childhood, but reported rates of hepatitis A can be paradoxically higher owing to transmission to older age persons, who are more likely to have clinically overt disease. A gradient from northern to southern Europe exists, in which hepatitis A is almost nonexistent in Scandinavian countries but relatively prevalent in Mediterranean countries.<sup>2</sup> The rates of hepatitis A in the United States have been decreasing gradually over the past several decades, probably as a result of improvement in water supplies, sewage disposal, and reduced crowding.<sup>8</sup>

Occasionally, large foodborne outbreaks occur, such as in Shanghai in 1988, associated with ingestion of raw shellfish.<sup>9</sup>

In the early 1980s, an increase in the number of injection-drug users with hepatitis A was observed in the United States. This increase reached a peak in 1986, when 19% of reported cases of hepatitis A were associated with intravenous drug abuse<sup>10</sup> and likely reflects parenteral transmission of the virus. In 1991, there was a marked increase in the number of cases of hepatitis A reported among homosexual men in the United States, Canada, and Australia, probably related to sexual practices.<sup>11</sup> The mechanism of transmission of hepatitis A in this setting is likely due to oral-anal contact.<sup>9</sup> In serologic surveys, anti-HAV-positive persons reported more frequent oral-anal contact, longer duration of homosexual activity, and a larger number of sexual partners than persons without serologic evidence of HAV infection.<sup>12,13</sup> Outbreaks of hepatitis A have been reported in health care personnel working in a burn unit<sup>14</sup> and in neonatal intensive care units.<sup>15</sup> Transmission of HAV by blood transfusion is rare, but donors in the prodromal phase of infection have been shown to transmit the virus by this route.<sup>15-17</sup> Approximately 50% of patients do not have a source identified for their infection.<sup>18</sup> In the United States, anti-HAV prevalence varies directly with age: Among persons 6 to 11 years of age, the prevalence is 9%; 20 to 29 years of age, 19%; 40 to 49 years of age, 33%; and greater than 70 years of age, 75%.<sup>19</sup> Anti-HAV prevalence is inversely related to income and household size.<sup>19</sup> In developing countries, the disease is hyperendemic, and most infections occur early in childhood.<sup>8,20</sup> Different patterns of antibody prevalence may be seen in populations belonging to high and low socioeconomic status from the same developing country.

- Low

## DISEASE

Hepatitis A is very often a subclinical infection of the liver, usually running an anicteric course, particularly in children. The likelihood of having symptoms with HAV infection is related to the person's age. In children less than 6 years of age, most (70%) infections are asymptomatic; if illness does occur, it is not usually accompanied by jaundice. Among older children and adults, infection is usually symptomatic, with jaundice occurring in greater than 70% of patients.<sup>21</sup> Most cases occur 2 to 6 weeks following exposure to the virus (incubation period). HAV has been documented in stool samples 2 to 3 weeks prior to the development of symptoms. The disease course is usually benign, starting with a mild prodromal phase appearing 1 to 7 days prior to the onset of dark urine,<sup>17</sup> including flulike symptoms, fever, malaise, anorexia, and nausea induced by fatty foods or tobacco. Most patients seek medical attention when they experience dark urine (choloria), which is followed by light-colored stools and jaundice. On physical examination, tender hepatomegaly may be present, and splenomegaly can be detected in about 15% of cases. In a significant proportion of patients, the appearance of jaundice is associated with rapid resolution of symptoms. The duration of illness is variable but usually lasts about 3 weeks. Prematurely born infants have been reported to shed HAV for longer periods than adults, possibly up to several months after the onset of illness.<sup>22</sup> Hepatitis A may run a protracted course, and in some cases, jaundice can last 12 to 18 weeks, with marked pruritus and fever (cholestatic hepatitis),<sup>23</sup> but recovery is the rule, and there are no chronic sequelae in the liver.<sup>24</sup> Relapsing hepatitis A can occur, in which exacerbations of symptoms and liver test abnormalities are found weeks to months after the onset of acute illness, but complete resolution is anticipated as well. Chronic shedding of HAV in feces does not occur; however, shedding can occur in persons who have relapsing illness.<sup>25</sup> Extrahepatic manifestations of hepatitis A are uncommon. Cutaneous vasculitis with IgM deposits,<sup>26</sup> cryoglobulinemia,<sup>27</sup> and cholecystitis<sup>28</sup> have been reported, along with neurologic syndromes such as Guillain-Barré, myelopathy, mononeuritis, meningoencephalitis, or exacerbation of pre-existing multiple sclerosis.<sup>29</sup> Hepatitis A infection can also behave as a triggering factor for autoimmune hepatitis, which should be suspected in patients with persistently elevated aminotransferase levels months after the resolution of the icteric phase.<sup>30</sup> The age at the time of diagnosis is an important determinant of prognosis.<sup>31,32</sup> Infection in the very young is associated with an asymptomatic or mild infection, although fulminant cases occur in very young children, whereas infection in adults older than 50 years of age is more likely to be associated with a fulminant course. Warning signs of this complication include irritability, changes in sleep pattern, and confusion. Although not at increased risk for HAV infection, persons who have chronic liver disease of any etiology are at increased risk for fulminant hepatitis A<sup>33,34</sup> should they become infected.

## PATHOGENESIS AND IMMUNITY

HAV is transmitted by the fecal-oral route, possibly replicating initially in the epithelial cells of the small intestine, after which it reaches the liver through the portal circulation.

The liver is the major site of replication, which occurs in the hepatocyte.<sup>35</sup> After intrahepatocyte replication, the virus is shed into the sinusoids and biliary canaliculi, passing into the intestine and then being eliminated in feces. Extrahepatic sites of replication such as the oropharynx have been postulated,<sup>36</sup> but the disease is essentially confined to the liver. In cell culture, most HAV isolates are not cytopathic; thus the liver injury is most likely due to a cell-mediated immune response.<sup>31,37</sup> During acute HAV infection, viremia and fecal shedding of virus occur within days of infection and typically persist until the appearance of symptoms. Initially IgM is produced, followed by IgG, and they both function as neutralizing antibodies in vitro.<sup>31</sup> Anti-HAV IgG persists throughout life and confers complete protection against reinfection with HAV.

## DIAGNOSIS

Elevation of aminotransferase levels (ALT, AST) is a sensitive, although nonspecific, indicator of parenchymal liver damage. However, there is no correlation between clinical severity and degree of transaminase elevation. Prothrombin time prolongation is a sign of severity, especially when associated with changes in mental status. High levels of alkaline phosphatase are seen in cholestatic hepatitis. Serologic diagnosis requires measurement of immunoglobulin M to the HAV particle (IgM anti-HAV), which usually is present during the acute phase of illness, declining and becoming undetectable 3 to 6 months after the infection (Fig. 64-2). IgG anti-HAV becomes detectable during the acute phase, reaching high titers during convalescence, persisting for life and conferring permanent immunity. HAV RNA can be detected in the blood and stool of most persons during the acute phase of infection by use of nucleic acid amplification methods, and nucleic acid sequencing has been used to determine the relatedness of HAV isolates. However, these methods, available in only a limited number of research laboratories, generally are not used for diagnostic purposes.<sup>7</sup>

**FIGURE 64-2** Serologic diagnosis of hepatitis A. ALT, alanine transaminase; HAV, hepatitis A virus; anti-HAV, antibody to HAV. (From Hoofnagle JH, Di Bisceglie AM: Serologic diagnosis of acute and chronic viral hepatitis. *Semin Liver Dis* 11:73, 1991.)

## TREATMENT AND PROGNOSIS

There is no specific therapy for HAV infection, and management is essentially supportive. The identification of patients requiring liver transplantation becomes critical when there is development of hepatic encephalopathy, although even in fulminant cases spontaneous recovery occurs more frequently than in hepatitis B. With careful selection, the survival rate for fulminant hepatitis A patients after transplantation is 80%.<sup>38</sup> In uncomplicated cases of hepatitis A, there is no indication for admission to the hospital, and no data support prolonged bed rest or dietary restriction as measures that favorably affect the clinical course.

## PREVENTION AND CONTROL

Good hygiene practices, especially for persons who work in the food industry, are important. Travelers to endemic areas should be advised against eating raw and uncooked food, with particular emphasis on vegetables, shellfish, and impure drinking water. Immunoglobulin (IG) provides protection against hepatitis A through passive transfer of antibody. IG for both intramuscular administration (IGIM) and intravenous administration (IGIV) contains anti-HAV, but IGIM is the product used for the prevention of HAV infection. The only generally accepted indication for passive immunization with immunoglobulin before exposure (pre-exposure immunoprophylaxis) of hepatitis A is travel to endemic areas.<sup>39</sup> Serum levels of neutralizing antibodies persist for approximately 18 weeks. Whenever possible, immunoglobulin should be administered 2 weeks before departure. When used for pre-exposure prophylaxis, a dose of IG (0.02 mL/kg) administered intramuscularly (IM) confers protection for about 3 months, and a dose of 0.06 mL/kg IG administered IM confers protection for about 5 months. When administered within 2 weeks following an exposure to HAV (0.02 mL/kg IM), IG is greater than 85% effective in preventing hepatitis A.<sup>40</sup> Efficacy is greatest when IG is administered early in the incubation period; when administered later in the incubation period, IG often only attenuates the clinical expression of HAV infection.<sup>40</sup> Postexposure prophylaxis is recommended especially for close personal contacts such as household and sexual partners, regardless of the age of the contact. Immunoglobulin prophylaxis is not recommended for casual contacts of hepatitis A patients (i.e., at school or work). The recommended dose is 0.02 mL/kg IM within 2 weeks of exposure. No transmission of hepatitis B virus, HIV, HCV, or other viruses has been reported from IGIM.

In 1995, an inactivated hepatitis A vaccine (Havrix) was licensed by the Food and Drug Administration (FDA) in the United States for use in persons aged more than 2 years to prevent HAV infection.<sup>41</sup> Hepatitis A vaccine is not approved for use in children younger than 2 years of age because of concern that children who have passively acquired maternal antibodies will have a diminished response to vaccine.<sup>42</sup> It is recommended for travelers to endemic areas and other high-risk groups. Each milliliter of the Havrix vaccine for adults contains 1440 ELU (ELISA units) of viral antigen. The recommended dose for adults is 1 mL IM in the deltoid muscle, plus a 1-mL booster dose 6 to 12 months later.<sup>41</sup> Protective levels of specific humoral antibodies are detectable in 80% to 98% of adult recipients 15 days after the first dose and in 96% after 1 month.<sup>43</sup> Another inactivated hepatitis A vaccine

**Table 64-2** Hepatitis A Vaccines

	<b>Havrix</b>	<b>VAQTA</b>
Recommended dose	2–18 yr: 720 ELU >19 yr: 1440 ELU (1 mL)	2–17 yr: 25 units* >18 yr: 50 units
Approved schedule of administration	0, 6–12 mo (adults and children)	0, 6 mo (adults) 0, 6–18 mo (children)
Injection site	Deltoid	Deltoid
Duration of immunity	10–20 yr	10–20 yr

ELU, enzyme-linked immunosorbent assay units.

\*1 unit = 1 ng hepatitis A virus antigen.

(VAQTA) has been licensed in the United States, and comparative features of these two vaccines, which are similar with respect to their clinical attributes, are shown in Table 64-2.

Both licensed vaccines are highly immunogenic in persons aged 18 years of age or older when administered according to the recommended schedules.<sup>44,45</sup> Protective antibody levels develop in 94% to 100% of adults 1 month after the first dose. After the second dose, all persons have protective levels of antibody. On the other hand, in some studies, administration of hepatitis A vaccine to persons with HIV infection resulted in lower seroconversion rates and antibody concentrations.<sup>46,47</sup> Among HIV-infected men, those who respond to hepatitis A vaccination have significantly more CD4<sup>+</sup> T lymphocytes at baseline (540/ $\mu$ L) compared with those who do not respond (280/ $\mu$ L).<sup>47</sup> Estimates of antibody persistence derived from kinetic models of antibody decline indicate that protective levels of anti-HAV could be present for 20 years or longer.<sup>48</sup> Immunization policy should be tailored to the specific population. Persons at high risk for HAV infection, including homosexually active men, persons with multiple sexual contacts, and travelers to endemic regions, should consider immunization, as well as those at risk for severe disease if infected, such as those with chronic hepatitis C.<sup>49</sup> Pre vaccination screening for anti-HAV might be cost effective in high and intermediate endemic regions, but costs of testing and availability of vaccine should be taken into account.

In May 2001, the FDA licensed a combined hepatitis A and B vaccine (Twinrix) for use in persons aged 18 years or older.<sup>50</sup> Twinrix contains the antigenic components used in Havrix and Engerix-B. The antigenic components in Twinrix have been used routinely in separate single-antigen vaccines in the United States since 1995 and 1989 as hepatitis A and B vaccines, respectively (Table 64-3; see also Prevention of hepatitis B, in the following section). The efficacy of Twinrix is expected to be comparable to that of existing single-antigen hepatitis vaccines. The persistence of anti-HAV and anti-HBs following Twinrix administration is similar to that following single-antigen hepatitis A and B vaccine administration at 4 years' follow-up (unpublished data, GlaxoSmithKline Biologicals, 2001).

## Hepatitis B

Human hepatitis B infection is still a major health problem throughout the world. It may evolve into chronic hepatitis and is a common cause of cirrhosis and hepatocellular carcinoma.

**Table 64-3**    *Doses and Recommended Schedule for Combined Hepatitis A and B Vaccine*

Vaccine	Age Group	Antigens Used	Volume	No. of Doses	Schedule
Twinrix	18 years and older	Havrix (720 ELU) combined with Engerix-B (20 mg)	1.0 mL	3	0, 1, and 6 mo

Hepatitis B (“serum hepatitis”) emerged in importance in the first half of the 20th century with the increased use of syringes and needles for the treatment of syphilis and administration of insulin in diabetics.<sup>2</sup> Large epidemics of blood-borne hepatitis followed the administration of yellow fever vaccines containing human serum. The association of hepatitis B specifically with blood and blood products was recognized as distinct from hepatitis A in volunteer studies, and the agent was first transmitted to chimpanzees in the 1970s.

**AGENT**

Hepatitis B virus (HBV) is a member of the family Hepadnaviridae, genus *Orthohepadnavirus*. Other hepadnaviruses have been described in the woodchuck, ground squirrel, tree squirrel, and domestic duck. The hepadnaviruses are a family of hepatotropic, DNA-containing viruses that share several features. Morphologically, the intact virions are 42 nm in diameter and frequently found in association with 20-nm, DNA-free, spherical and tubular particles containing the surface glycoprotein (HBsAg).<sup>51</sup> Humans cannot be infected by the nonhuman hepadnaviruses. There is an inner nucleocapsid, composed mainly of a phosphoprotein, hepatitis B core antigen (HBcAg), which forms active complexes with the viral polymerase that generates the mature double-stranded DNA genome. HBcAg also plays a role in packaging pregenomic RNA. The HBV genome is composed of circular DNA (Fig. 64-3) that is only partially double-stranded.<sup>52</sup> Based on comparisons of nucleotide sequences, the HBV sequences have been classified into eight genotypes at present, named A through H,

with important geographic and clinical differences<sup>53–55</sup> (see Epidemiology).

One DNA strand is complete except for a small nick (the minus strand), while the other is incomplete (the plus strand). Minus-strand DNA is synthesized from an RNA template, the “pregenome,” by reverse transcription, while plus-strand DNA is transcribed within the nascent virus particle from packaged minus-strand DNA. Both reactions are catalyzed by the same virally encoded enzyme, the HBV DNA polymerase, which is packaged within virus particles. Transcription of plus-strand DNA is terminated upon exit of the virus particle from the cell and completed only upon entry into a new cell at the beginning of the virus life cycle. Minus-strand DNA directs the transcription of messenger sense RNAs containing four overlapping reading frames that encode the structural proteins (the surface, or envelope, protein and the core protein), the polymerase (pol), and a protein of uncertain function (X). Carefully regulated expression of the core protein reading frame leads to two distinct proteins:<sup>51,56</sup> the core protein itself (HBcAg) and a closely related polypeptide called hepatitis B e antigen (HBeAg). HBeAg is a soluble nonstructural protein with an ill-defined function, although its presence correlates with circulating HBV DNA in serum. The precore region of the core reading frame can undergo a G-to-A mutation, resulting in the formation of a stop codon at nt 1896 that abolishes the synthesis of HBeAg (precore mutant).<sup>54</sup> Expression of the surface protein reading frame (S) is similarly complex. The S reading frame includes an upstream pre-S region, which encodes two minor surface protein species, pre-S1 and pre-S2, that share a common carboxyl terminus with the major surface protein, HBsAg. These proteins are likely to contain sites for the binding of the HBV to hepatocytes and are highly immunogenic. There are data suggesting that the pre-S proteins appear in serum coincidentally with the period of active HBV replication and disappear when viral replication diminishes.<sup>57</sup> A third reading frame encodes the DNA polymerase, pol, which also has reverse transcriptase activity. A fourth reading frame, X, encodes the hepatitis B x antigen (HBxAg),<sup>55,58</sup> which in cell culture is a transcriptional transactivator capable of upregulating the expression of a number of genes.<sup>59</sup> HBxAg has been proposed to be an important factor in the tumorigenic potential of HBV, since it has been shown to exist in an integrated form within the genome of patients with chronic hepatitis B who develop hepatocellular carcinoma.<sup>59</sup>

The replication of the HBV genome involves four major steps<sup>51</sup>:

1. After viral entry, completion of plus-strand DNA synthesis and the formation of a fully double-stranded, covalently closed, circular DNA molecule (cccDNA)
2. Transcription of cccDNA into a slightly greater than genome-length RNA, the “pregenome,” by host RNA polymerase, as well as four to five shorter messenger

**FIGURE 64-3**    Hepatitis B genome. HBsAg, hepatitis B surface antigen; HBxAg, hepatitis B x antigen; HBcAg/HBeAg, hepatitis B core antigen/hepatitis B e antigen. (From Koff RS, Dienstag GL, Riely CA, et al: AGA Clinical Teaching Project, Unit 3, Viral Hepatitis, 2nd ed. Timonium, Md., Milner-Fenwick, 1994.)

RNAs encoding the various proteins expressed by the virus

3. Synthesis of new minus-strand DNA by reverse transcription of the RNA pregenome RNA
4. Synthesis of new plus-strand DNA utilizing minus-strand DNA as a template, commencing after particle assembly but prior to release of the newly replicated particle from the cell

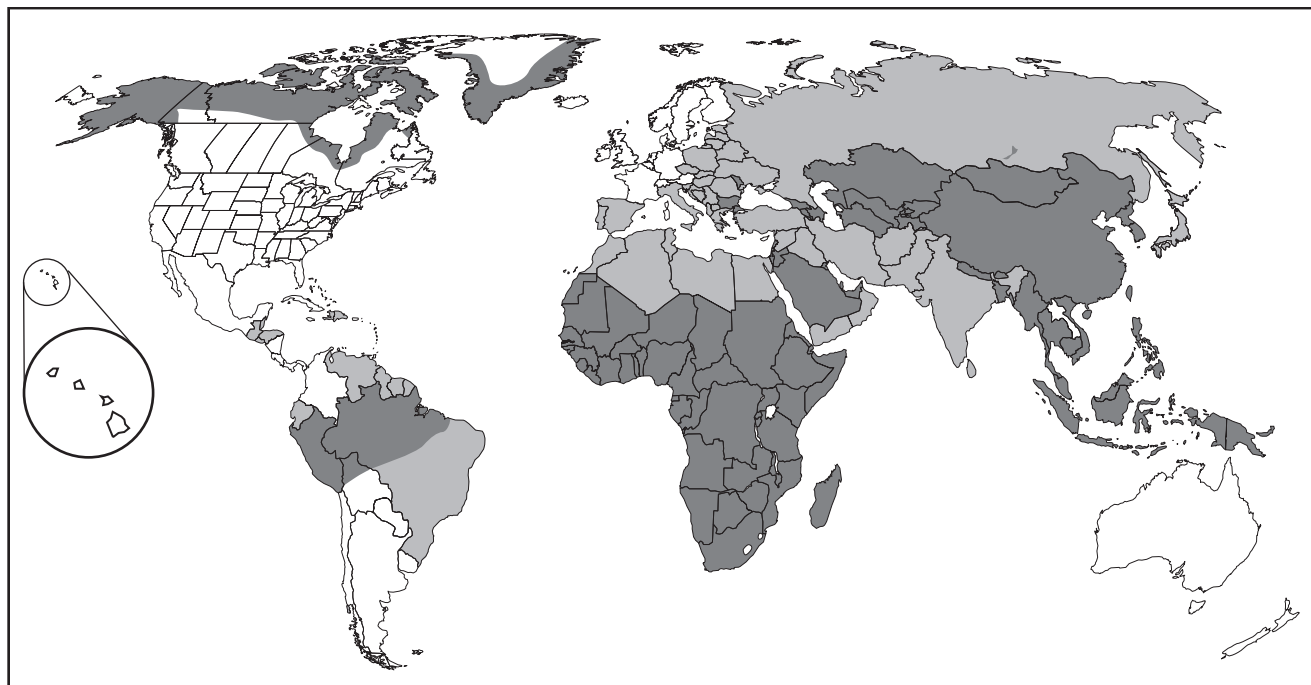

HBV infection begins with the attachment of the virion to the surface of the hepatocyte.<sup>60</sup> Subsequently, the cccDNA generated within the host cell nucleus is transcribed to pregenomic and subgenomic viral RNAs by host RNA polymerase. Translation of this pregenomic RNA leads to the production of pol and core proteins.<sup>60</sup> This pregenomic RNA is encapsidated into viral nucleocapsid core particles. The encapsidation mechanism is highly selective for genomic RNA, and depends on a region located near the 5' end of the genome called the  $\epsilon$  signal.<sup>61</sup> The  $\epsilon$  region at the 5' end of the pregenomic RNA interacts with the pol protein.<sup>62</sup> This pol- $\epsilon$  interaction is stabilized by the host's heat shock protein 90 (Hsp 90). The core proteins dimerize around the pregenomic RNA pol complex and form the viral nucleocapsids. Once the pregenomic RNA is packed into a nucleocapsid, it serves as a template for reverse transcription and minus-strand DNA synthesis. The pol protein is bound to the 5'- $\epsilon$  end and starts synthesizing the first three nucleotides of the minus-strand DNA. This nascent DNA chain is in turn translocated to the 3' end of the pregenomic RNA, binding to a 12-nucleotide complementary

region called direct repeat 1 (DR1). Subsequently, minus-strand DNA synthesis continues, and the template pregenomic RNA is degraded by the RNaseH activity of the pol protein except for the last few nucleotides.<sup>63</sup> These RNA oligomers are translocated to the 3' copies of another 12-nucleotide segment called direct repeat 2 (DR2), from which the synthesis of the plus strand DNA is initiated. The nucleocapsid containing the partially double-stranded DNA is directed to the endoplasmic reticulum and Golgi apparatus for virion assembly. The characteristic partially double-stranded genome (with a large gap in the plus strand) results from premature termination of plus-strand synthesis by the pol protein.

Mutations are introduced into the viral genome probably as a result of errors during reverse transcription during replication. An unusual serologic pattern, clinically characterized by rapidly progressive liver failure, was described for the first time by Chu and associates in 1987.<sup>64</sup> These investigators reported on patients who had measurable HBV DNA in serum in the absence of detectable HBeAg. The term anti-HBe antigen-negative hepatitis B is currently used to describe this special category of infection with HBV, which typically results from mutation in the precore region of the genome (see Epidemiology and Disease).

## EPIDEMIOLOGY

The prevalence of HBV varies widely in different parts of the world. Approximately 350 million people are chronic

### Hepatitis B

#### HBsAg Prevalence

- ≥8%—High
- 2-7%—Intermediate
- <2%—Low

**FIGURE 64-4** Risk of developing chronic hepatitis B virus (HBV) infection in relationship to age at the time of HBV infection. The highest risk occurs early in life. (From Koff RS: Viral hepatitis. In Schiff L, Schiff ER [eds]: Diseases of the Liver, 7th ed. Philadelphia, JB Lippincott, 1993, p 537.)

carriers of the virus, and about three quarters of these live in Asia.<sup>1,65</sup> Chronic HBV infection is found in 6% to 10% of adults with evidence of infection, approximately 25% of infected children aged 1 to 5 years, and 70% to 90% of infected infants<sup>66,67</sup> (Fig. 64-4). This reflects a greater proportion of acute infection progressing to persistence among the very young. Generally speaking, probably less than 1% of new infections in healthy adults result in viral persistence for more than 6 months. Transmission of HBV from an infected mother to her infant during birth (perinatal or vertical transmission) results in the highest rate of persistent infection. In Asia perinatal infection accounts for about 15% to 20% of chronic HBV infections in adults, and this correlates well with the prevalence of HBsAg-positive mothers. Perinatal transmission is known to occur at a lower rate in HBeAg-negative mothers.<sup>68,69</sup>

Horizontal transmission among young children is common in highly endemic regions, while sexual transmission of HBV dominates in well-developed countries with lower overall prevalence of the infection. Bloodborne infection is also common among illicit injection drug users. HBsAg has been found in blood and various body fluids, such as saliva, menstrual and vaginal discharges, seminal fluid, colostrum, breast milk, and serous exudates, and these have been implicated as vehicles of transmission of the infection.<sup>70</sup> A cross-sectional seroprevalence study conducted to assess the frequency of HBV infection among children born in the United States to Southeast Asian refugees showed that about 7% of the young children of HBsAg-negative mothers were infected with HBV, suggesting that child-to-child transmission remains an important route of infection among this group.<sup>71</sup> Among Alaskan Eskimos, the highest incidence of HBV infection occurs during the first 5 years of life,<sup>72</sup> and chronic infection rates can range from 5% to 10%, a phenomenon similar to that described in the Middle East.<sup>73</sup> In the United States, the incidence of hepatitis B reached a plateau and began to decrease after the mid-1980s, probably as a result of intensive efforts to control the spread of human immunodeficiency virus (HIV) in the same

high-risk populations.<sup>2</sup> An epidemiologic study conducted in the United States between 1981 and 1988 showed that the proportions of hepatitis B cases accounted for by homosexual activity decreased by 62%, whereas the proportion of cases acquired by heterosexual exposure increased by 38%.<sup>66</sup> In another study conducted on attendees at a sexually transmitted disease clinic and college students, the risk of acquiring HBV infection was increased with increasing number of sexual partners. The prevalence of HBV infection was 6% for those with fewer than five recent partners (in the past 4 months) versus 21% for those with five or more partners.<sup>67</sup>

The proportion of hepatitis B patients with a history of parenteral drug use increased by 80% in the United States between 1981 and 1988.<sup>66</sup> In the same study, a decline of 75% in the number of health care workers reported with hepatitis B reflects the positive impact of HBV immunization and implementation of universal blood precautions. Additional possible risk factors for the transmission of HBV infection include traditional tattooing, bloodletting, and ritual circumcision. Results of investigations on the role of biting insects do not support a significant role in viral transmission. Even though HBsAg has been detected in some mosquito species and other arthropods, no convincing evidence for replication of HBV in insects has been obtained.<sup>70</sup> HBV is not transmitted by the fecal-oral route, and urine is not infectious unless contaminated with blood. There is no evidence that airborne infections occur.

Table 64-4 summarizes the prevalence of serologic markers for HBV among well-defined population groups at risk. They should be screened for HBV infection and immunized if seronegative.<sup>74</sup>

High rates of infection occur in northern Africa, sub-Saharan Africa, the Arabic Middle East, Southeast Asia, the Philippines, Polynesia, Indonesia, Eskimo populations throughout the Arctic,<sup>68</sup> and the Amazonian Basin of South America.<sup>75</sup> In South America, the prevalence of HBsAg increases from south to north, from 0.5% to 1.1% in Chile, Argentina, Uruguay, and southeastern Brazil to moderate rates (1.5% to 3%) in mid and northeastern Brazil.<sup>75</sup> A remarkably high prevalence has been noticed in the central Amazonian region (5% to 15%) as well as some areas in Colombia, Peru, and Venezuela. In Central America the prevalence of HBsAg

**Table 64-4** Prevalence of HBV Serologic Markers in Population Groups That Should Be Screened for HBV infection

Population	Prevalence of HBV Serologic Markers (%)	
	HBsAg	All Markers
Persons born in endemic areas	13	70–85
Men who have sex with men	6	35–80
Injecting drug users	7	60–80
Dialysis patients	3–10	20–80
HIV-infected patients	8–11	89–90
Pregnant women (USA)	0.4–1.5	
Family/household and sexual contacts	3–6	30–60

is low to moderate (1% to 3%) as in Mexico or the Caribbean, except in the Dominican Republic and Haiti, where there is a prevalence of about 4%. The high-risk groups for HBV are similar to the ones in United States and in Canada. Most of the HBsAg carriers in the world are HBeAg negative.<sup>76</sup> In some community-based studies from different countries, the prevalence of HBeAg negativity in chronic HBV infection has been found to range between 70% and 100%.<sup>77-79</sup> The frequency of precore mutants is determined mainly by the infecting HBV genotype. The non-A genotypes (B through H), particularly D, are highly prevalent in the Mediterranean region, where the vast majority of HBV-infected persons are HBeAg negative.<sup>80</sup> In Japan genotypes B and C are the most frequently reported, with no significant differences regarding clinical behavior.<sup>81</sup> However, recent unpublished studies suggest differences in their response to treatment, with genotype B associated with slower progression to cirrhosis and hepatocellular carcinoma (HCC) and less likely to relapse on lamivudine. Furthermore, response to pegylated interferon is better in genotypes A and B than in genotypes C and D. A recent study carried out in the United States on 694 patients with chronic HBV showed the presence of seven genotypes (A through G).<sup>82</sup> Two thirds of the patients in this study were born outside the United States. The genotype prevalence were as follows: A, 34.7%; B, 22%; C, 30.8%; D, 10.4%; E, 0.4%; F, 0.6%; G, 1.1%. In this study, the precore variant was more common in genotypes D (73%) and B (46%). Genotypes B and C were predominant among patients with vertical transmission, genotype A was prevalent among patients with acquisition of the infection by sexual or parenteral routes, and genotype D was related to all modes of transmission. The influx of immigrants from countries with a high prevalence of HBV infection in the past few decades may have altered the epidemiology of HBV infection in the United States.<sup>82</sup>

## DISEASE

Acute infection with HBV is symptomatic in about 50% of adult cases. In symptomatic cases, after an incubation period of 2 to 6 months (average, 75 days), prodromal symptoms such as nausea, anorexia, fever, and vague abdominal discomfort may occur, and these are indistinguishable from acute hepatitis episodes of any other etiology. Seventy-five percent of patients with acute hepatitis B have an anicteric course. In most instances, jaundice appears after all the prodromal symptoms are resolved, and it rarely lasts longer than 4 weeks, although cholestatic courses occur occasionally. Extrahepatic manifestations such as urticaria and arthritis may precede acute hepatitis B and are usually associated with immune complexes. In chronic hepatitis B, polyarteritis nodosa is classically described, with immune complexes containing HBsAg being found in vascular lesions.<sup>83</sup> Polymyalgia rheumatica and glomerulonephritis also occur in association with hepatitis B, and in the latter immune complexes containing HBsAg and HBeAg are present in the glomerular and capillary basement membranes.<sup>84</sup> Neurologic manifestations such as Guillain-Barré syndrome, periarteritis nodosa affecting the vasa nervorum, polyneuropathy, mononeuropathy, and tonic-clonic seizures have been described in association with HBV infection, but they are rare.<sup>29</sup>

Immunocompetent adults can clear HBsAg from serum within 6 months in more than 99% of cases. Patients who are

only moderately immunocompromised may have a high rate of chronicity (defined as persistence of HBsAg in serum for more than 6 months) including neonates, hemophiliacs, intravenous drug users (IVDUs), patients on hemodialysis, organ recipients, and HIV-infected persons.<sup>74</sup> Seventy to 90 percent of persons with chronic HBV infection have normal aminotransferase levels.<sup>85</sup> The clinical course of HBsAg carriers is generally benign. De Franchis and colleagues followed 69 HBsAg carriers for 10 years, and only one developed histologic progression to more advanced stages.<sup>85</sup> No patient developed HCC or died of liver disease. Nonetheless, the classic studies of Beasley and co-workers in Taiwan demonstrated a markedly increased risk (>100-fold) of HCC in HBsAg-positive male adults compared with those who were HBsAg negative.<sup>86</sup> An Austrian study of HBsAg carriers showed that only 1.6% developed chronic active hepatitis or cirrhosis during follow-up.<sup>87</sup> In that study, despite the lack of symptoms, physical findings, or aminotransferase elevations, abnormal liver histologic findings were reported in 5% of patients, and one developed HCC. In a 16-year follow-up study of 317 HBsAg-positive blood donors from Montreal, only three died of HBV-related cirrhosis, and none developed HCC.<sup>88</sup> There are data to suggest that HBsAg carriers are more susceptible to alcohol-related liver damage than the general population and should abstain from alcohol.<sup>89</sup>

Chronic infection is more commonly observed in patients with minimal or no clinical manifestations during the acute phase, whereas patients with florid, severe acute icteric hepatitis B tend to clear the virus and recover completely. The clinical course of chronic hepatitis B is usually characterized by an asymptomatic state or a paucity of symptoms. Some patients may first come in with advanced liver disease, namely, ascites, variceal bleeding, jaundice, coagulopathy, or hepatic encephalopathy, indicative of an ominous course. The estimated 5-year rates of progression are as follows: chronic hepatitis to cirrhosis, 12% to 20%; compensated cirrhosis to hepatic decompensation, 20% to 23%; compensated cirrhosis to HCC, 6% to 15%.<sup>90,91</sup>

Fulminant hepatitis is a rare but potentially catastrophic event among HBV-infected patients. It occurs in approximately 0.1% of all acute hepatitis B cases and accounts for about 50% of all cases of fulminant viral hepatitis.<sup>32</sup> The fulminant course is believed to be caused by massive destruction of infected hepatocytes by the immune system. It is postulated that HBV mutations play a role in the development of fulminant hepatitis—inducing enhanced virus replication or perturbing the immune response.<sup>92,93</sup> Encephalopathy is the hallmark of the syndrome, usually detected less than 8 weeks from onset of disease, and is associated with worsening coagulopathy. Long-term prognosis of patients with HBeAg-negative chronic HBV infection is poor, with greater mortality and development of HCC compared with their HBeAg-positive counterparts.<sup>76</sup>

There is a strong correlation between the occurrence of chronic hepatitis B infection and primary HCC. The worldwide distribution of the incidence of HCC correlates with the prevalence of the HBsAg carrier state, which has been well demonstrated in case-control studies.<sup>87</sup> In China, where the HBsAg carrier prevalence can be as high as 14%, mortality from HCC is 17 per 100,000 population, whereas in regions of low HBsAg prevalence, such as the United Kingdom, mortality from HCC is 1 per 100,000.<sup>87</sup> Cirrhosis is not necessarily a

sine qua non for development of HCC, since it may occur in noncirrhotic livers, where HBV-DNA seems to be integrated into the malignant hepatocyte. However, the presence of cirrhosis appears to represent a premalignant condition regardless of its etiology. The mechanisms by which this occurs are not known, but changes in the microcirculation of the liver, with delivery of oncogenic materials such as nitric oxide to selected groups of hepatocytes, or interference with the normal maturing of hepatocytes from the portal areas to the centrilobular areas may play a role. Nitric oxide can induce DNA damage in hepatocytes.<sup>94</sup>

## PATHOGENESIS AND IMMUNITY

The mechanisms of viral clearance, reasons for persistence of HBV, and oncogenic potential are incompletely understood. The envelope gene contains three in-phase translation initiation codons, which determine the pre-S1, pre-S2, and S antigens. During acute, self-limited HBV infection, there is a vigorous CD4<sup>+</sup> T-cell response directed against multiple epitopes within HBcAg, HBeAg, and HBsAg.<sup>31</sup> Under most circumstances, HBV and its proteins are not directly cytopathic to the hepatocytes. Liver injury in acute hepatitis B is thought to be mediated by cytotoxic T lymphocytes, which attack HBV-infected hepatocytes. After HBV infection of the hepatocyte, HBcAg and other viral peptides are presented on the cell surface in association with HLA class I protein. This HLA class I-HBcAg complex is recognized by specific cytotoxic CD8<sup>+</sup> T lymphocytes, which trigger hepatocyte death. Many questions concerning the pathogenesis of hepatitis B and the elimination of HBV remain unanswered, however, and substantial data suggest that virus clearance may depend largely on non-cytolytic, cytokine-mediated antiviral mechanisms. There is also much uncertainty about mechanisms leading to priming of T-cell responses in the liver, as well as the activity and fate of intrahepatic cytotoxic CD8<sup>+</sup> T cells.

Nonetheless, it is clear that the natural course of chronic HBV infection is determined by the interplay between virus replication and host immune response. Chronic HBV infection consists of two phases: an early replicative phase with active liver disease and a late nonreplicative phase with remission of liver disease.<sup>95</sup> Patients with perinatally acquired disease exhibit an additional phase (immune tolerance) in which replication is not associated with active liver disease. In these patients, the initial phase is characterized by high levels of HBV DNA in serum and presence of HBeAg but generally normal ALT levels and liver histology. The immune tolerance phase usually lasts between 10 and 30 years, with a very low spontaneous rate of HBeAg clearance.<sup>96</sup> This low rate of viral clearance is probably the main reason for the high frequency of vertical transmission among young adults and adolescents in Asian countries. In patients with perinatally acquired HBV infection, transition from the immune tolerant to the immune clearance phase occurs after two or three decades. Spontaneous HBeAg clearance occurs in a small percentage of patients each year.<sup>96</sup> Sometimes it is accompanied by an increase in ALT or even exacerbation of symptoms of acute hepatitis, which may lead to the incorrect diagnosis of acute hepatitis B in patients not known to have chronic HBV infection.

Patients in the nonreplicative phase of chronic HBV infection are HBeAg negative and anti-HBe positive. They are also

HBV DNA negative. Some patients eventually become HBsAg negative, at a rate of 0.5% to 2% per year.<sup>97</sup> Patients who become HBsAg negative may be misdiagnosed as having cryptogenic cirrhosis if they were not previously known to have HBV infection. A European study on compensated cirrhosis patients with hepatitis B who cleared HBsAg showed much better prognosis than for persistent HBsAg antigenemia.<sup>98</sup> Recent data from Taiwan on 218 patients who underwent spontaneous HBsAg clearance and were followed for a median of 61.7 months revealed that only 1.6% developed cirrhosis and 1.1% developed HCC.<sup>99</sup> All these patients had concurrent infection with hepatitis C (HCV) or D (HDV) viruses. This study concluded that noncirrhotic patients without concomitant HCV or HDV infection have an excellent outcome after spontaneous HBsAg clearance in terms of HBV clearance and clinical disease progression compared with a persistently HBsAg-positive control group that experienced more significant elevation of ALT levels and cirrhosis/HCC development.

## DIAGNOSIS

The clinical course of acute or chronic hepatitis B infection is indistinguishable from other forms of viral hepatitis, and the diagnosis relies on serologic markers. The typical course of acute hepatitis B is shown in Figure 64-5. HBsAg is detectable in serum prior to the increase in aminotransferases or development of symptoms and remains detectable during convalescence. It becomes undetectable by the end of the fourth to sixth month following its appearance. The serologic presence of HBsAg beyond 6 months defines chronic hepatitis B. As HBsAg levels decline, anti-HBs appears in serum.<sup>57</sup> The presence of anti-HBs indicates recovery and immunity, since it is a neutralizing antibody. It is also the marker of successful vaccination against HBV.<sup>100</sup>

**FIGURE 64-5** Serologic diagnosis of acute hepatitis B virus (HBV) infection. Initially, HBV DNA can be detected by blot hybridization, but as the disease resolves only low levels detectable by polymerase chain reaction (PCR) can be demonstrated. ALT, alanine transaminase; HBsAg, hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBV DNA, hepatitis B virus deoxyribonucleic acid; anti-HBc, antibody to hepatitis B core antigen; anti-HBe, antibody to HBeAg; anti-HBs, antibody to HBsAg. (From Hoofnagle JH, Bisceglie AM: Serologic diagnosis of acute and chronic viral hepatitis. *Semin Liver Dis* 11:73, 1991.)

HBcAg, the main product of the nucleocapsid C gene, is a particulate antigen that is detectable in liver tissue in patients with acute or chronic hepatitis B. It is not found in serum and when detected in liver tissue may be a sensitive indicator of viral replication in chronic hepatitis B.<sup>101</sup>

HBeAg, the other product of the nucleocapsid gene, is soluble and becomes detectable in serum when HBsAg appears, and its presence correlates with active viral replication in the liver as well as a high degree of infectivity. HBeAg disappears from serum several weeks before HBsAg does in acute, self-limited infection, and it is not detectable in serum without HBsAg. In contrast, HBeAg may remain detectable in chronically infected individuals from months to years.

Anti-HBc appears at the onset of symptoms or aminotransferase elevations in acute hepatitis B and persists for life. IgM anti-HBc is detected at the beginning of acute hepatitis B and persists for 3 to 12 months.<sup>102</sup> The conventional immunoassay for IgM anti-HBc can detect this antibody only when present in high titers, but in many cases of chronic hepatitis B, where IgM anti-HBc levels are low, it may not be detectable.<sup>102</sup> In a patient with acute hepatitis and HBsAg detectable in serum, the finding of IgM anti-HBc suggests acute hepatitis B. Detection of IgG anti-HBc only suggests past infection with HBV. HBV vaccine recipients do not develop anti-HBc, so the presence of this antibody helps in the differentiation between successful vaccination and HBV infection.

Antibody to HBeAg (anti-HBe) is detectable as HBeAg disappears from the serum. Its presence during early acute infection is a reliable predictor of spontaneous resolution of acute infection, even when HBsAg is still present.<sup>103</sup> In chronic hepatitis B, the loss of HBeAg and acquisition of anti-HBe is associated with biochemical and histologic improvement. The typical course of a chronic hepatitis B infection is shown in Figure 64-6.

HBV DNA is detectable in serum during acute and chronic HBV infections. Dot blot hybridization assays allow detection of HBV DNA at levels of 10 to 500 pg/mL, which represent approximately  $10^6$  genome-equivalents/mL.<sup>57</sup> The polymerase chain reaction (PCR) is an extraordinarily sensitive technique

for detecting HBV-DNA, and it is capable of detecting as few as 10 to 50 genome equivalents/mL.<sup>58</sup> False positivity is the main drawback of this sensitive assay owing to the possibility of minute contamination of the samples being tested. Clearance of HBV DNA from the serum during acute and chronic hepatitis B indicates resolution of active viral replication.<sup>103</sup>

The role of histopathology in the diagnosis of acute hepatitis B is not one of critical importance, since there is no correlation between clinical course and histologic severity in a given case. The hepatic lesions in acute viral hepatitis in general are characterized by hepatocyte necrosis in conjunction with acute and chronic inflammatory cellular infiltrates. There is intense inflammation predominantly in the portal areas, although the pericentral area (zone 3) may exhibit necrosis. The reticular framework typically is preserved in acute viral hepatitis. The histologic spectrum of chronic hepatitis B is wide. Piecemeal necrosis is defined as the appearance of destroyed hepatocytes and lymphocytic infiltration at the interface between the limiting plate of periportal hepatocyte parenchymal cells and portal tracts (interface hepatitis). Individual hepatocytes can exhibit cell death with shrinkage and eosinophilic staining, referred to as Councilman bodies.

The old morphologic classification of chronic hepatitis, in which “chronic persistent,” “chronic active,” and “chronic lobular” hepatitis were described as different staging categories of inflammation, has been replaced by new schemes that embrace etiology, grade, and stage.<sup>104,105</sup> This involves specification of etiologic agent (viral, drug-induced, autoimmune, metabolic), grading related to degree of necrosis and inflammation, staging regarding degree of fibrosis, bridging necrosis, cirrhosis, and degree of severity (mild, moderate, or severe), all of which imply a clinical-histologic correlation. Box 64-1 summarizes the recommendations for the evaluation of the patients with chronic HBV infection.

## TREATMENT AND PROGNOSIS

### Interferon

There is no specific treatment for acute viral hepatitis B. Since infection is, for the most part, self-limited, complete spontaneous recovery is the rule for well over 95% of patients. By the time jaundice and symptoms are present in acute hepatitis B, viral replication is usually decreasing and may have actually ceased.<sup>58</sup> Alpha interferon (IFN- $\alpha$ ) was studied in a randomized, placebo-controlled fashion in Greece among patients with acute icteric hepatitis B.<sup>106</sup> This study failed to show any difference between the groups regarding loss of HBsAg and HBeAg from the serum, resolution of symptoms, and normalization of aminotransferases. There were no deaths from fulminant hepatic failure or development of chronicity.

The association between chronic HBV infection and progression to cirrhosis and HCC makes therapy for chronic hepatitis B a real necessity. IFN- $\alpha$  has been shown to be an efficacious antiviral agent in the treatment of some patients with chronic HBV infection. Interferons are a heterogeneous family of proteins grouped according to structure, antiviral effects, and immunomodulatory properties. IFN- $\alpha$  is produced by B lymphocytes and monocytes in response to viruses and certain stimulations. IFN- $\alpha$  may act in viral hepatitis by several mechanisms. It induces expression of several hundred

**FIGURE 64-6** Serologic diagnosis of chronic hepatitis B virus (HBV) infection. Ultimately, there is a remission in disease when seroconversion from HBeAg to anti-HBe occurs. See Figure 64-5 for abbreviations. (From Hoofnagle JH, Biscaglia AM: Serologic diagnosis of acute and chronic viral hepatitis. *Semin Liver Dis* 11:73, 1991.)

**Box 64-1** Recommendations for the Evaluation of Patients with Chronic HBV Infection**Initial Evaluation**

History and physical examination

Laboratory tests to assess liver disease: complete blood cell count with platelets, hepatic panel, and prothrombin time

Tests for HBV replication: HBeAg/anti-HBe, HBV DNA

Tests to rule out other causes of liver disease: anti-HCV, anti-HDV

Tests to screen for HCC: AFP and US in high-risk patients

Liver biopsy to grade and stage liver disease: for patients who meet criteria for chronic hepatitis

**Suggested Follow-Up for Patients not Considered for Treatment**

HBeAg-positive chronic hepatitis B with HBV DNA  $\geq 10^5$  copies/mL and normal ALT level

ALT every 3 to 6 mo

Consider liver biopsy and/or treatment when ALT levels become elevated

Consider screening for HCC in relevant populations

Inactive HBsAg carrier state

ALT every 6 to 12 mo

If ALT levels become elevated, check serum HBV DNA and exclude other causes of disease

Consider screening for HCC in relevant populations

AFP,  $\alpha$ -fetoprotein; anti-HCV, antibody to hepatitis C virus; anti-HDV, antibody to hepatitis D virus; anti-HBe, antibody to HBeAg; HBV, hepatitis B virus; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HCC, hepatocellular carcinoma; US, ultrasound. Adapted from Lok ASF, McMahon BJ: Chronic hepatitis B: AASLD Practice guidelines. *Hepatology* 34:1225, 2001.

intracellular proteins that convey antiviral properties to the cell, reducing viral DNA, RNA, and protein synthesis and amplifying adaptive (cytotoxic T lymphocytes) and innate (natural killer cells) immune responses to viral proteins.<sup>107,108</sup> Recombinant IFN- $\alpha$ -2b was approved by the FDA in 1992 for use in chronic HBV infection. The recommended dose is 5 million units (mU) SQ daily or 10 mU three times a week for 24 weeks. The side effects of IFN- $\alpha$  are summarized in Box 64-2.

**Box 64-2** Side Effects of Alpha Interferon

**General:** fatigue, fever, anorexia, weight loss, myalgias, arthralgias, increased susceptibility to bacterial infections

**Neuropsychiatric:** anxiety, depression, mood swings, irritability, headache, sleep disturbances, suicidal ideation, seizures, acute psychosis, coma

**Gastrointestinal:** nausea, vomiting, diarrhea, abdominal discomfort, decompensation of liver disease

**Hematologic:** cytopenias

**Dermatologic:** rash, alopecia, local reaction at injection site

**Miscellaneous:** hyperthyroidism, hypothyroidism, exacerbation of any autoimmune disease

Interferon is indicated for HBeAg-positive chronic hepatitis B with elevation of ALT. A large meta-analysis of 15 randomized, controlled trials showed a rate of HBV DNA clearance of 37% in treated patients versus only 17% in untreated controls.<sup>109</sup> Approximately 60% to 70% of IFN responders have a sudden increase in serum aminotransferase levels during the second to third month of therapy, which is attributed to the immunostimulating properties of this drug. Before initiating IFN, it is often recommended to follow the patients for at least 4 to 6 months to identify those who may spontaneously seroconvert to anti-HBeAg, which will occur in 5% to 10% of patients who are initially positive for HBeAg.<sup>110</sup> IFN is contraindicated in patients with decompensated cirrhosis, since these individuals are at risk for further decompensation.<sup>111</sup> However, it is a safe drug when given to patients with compensated cirrhosis. In fact, some clinical trials in patients with HBeAg-positive chronic hepatitis have included up to 60% of biopsy-proved cirrhotics, and fewer than 1% of them developed decompensation.<sup>112</sup> High pretreatment aminotransferase levels ( $>3$ –4 times the upper limit of normal), low HBV DNA ( $<200$  pg/mL by solution hybridization), and active disease on liver biopsy are the best predictive factors for favorable response to IFN.<sup>113</sup> The definition of complete response to therapy usually implies sustained loss of HBeAg and HBV DNA, with normalization of ALT for at least 6 months after therapy.<sup>114</sup> This occurs in approximately 25% to 40% of patients.<sup>109</sup> However, loss of HBsAg occurs in only about 8% to 10% of patients.<sup>113</sup> IFN-induced HBeAg clearance is durable in 80% to 90% of patients after a follow-up period of 4 to 8 years.<sup>115,116</sup> Sustained virologic response usually correlates with histologic improvement, but residual hepatic injury can occur.<sup>117</sup> The rationale for administering a short course of corticosteroids (“prednisone priming”) prior to IFN therapy is that recovery of immune function following steroid withdrawal may enhance the response to IFN. However, a meta-analysis of seven controlled trials failed to show any benefit of steroid priming.<sup>118</sup> Therefore, this practice is not recommended as adjuvant therapy for chronic HBV infection.

In patients with HBeAg-negative HBV infection, initial biochemical and virologic response is not maintained after therapy ceases.<sup>119</sup> Higher doses of IFN for longer periods of time are not associated with higher rates of sustained virologic response.<sup>120</sup> Patients with normal or near-normal ALT levels are usually poorly responsive to IFN therapy; fewer than 10% respond to therapy.<sup>121</sup> These patients are considered to be in an HBsAg carrier state and should be followed periodically.<sup>122</sup>

The fact that IFN is effective in fewer than 40% of patients with chronic HBV infection and is associated with many side effects dictates the need for alternative treatments. Encouragingly, pegylated interferon is proving to be more effective than standard interferon.

**Lamivudine**

Lamivudine (3-TC), a nucleoside analog, is an oral 2'-3'-dideoxynucleoside that inhibits viral DNA synthesis, interfering with the reverse transcriptase and DNA polymerase activities of the pol protein. The clinical efficacy of lamivudine in patients with hepatitis B was observed for the first time incidentally in the course of treating HIV in a group of patients infected by both viruses.<sup>123</sup> Because replication of HBV requires conversion

of an RNA intermediate to relaxed, circular, partially double-stranded DNA (see the preceding Agent section), its DNA polymerase functions as a reverse transcriptase. The polymerase (P) gene is the largest, encoding a protein of 832 amino acids.<sup>124</sup> Within the active site of the polymerase lies a highly conserved amino acid motif consisting of the sequence Tyr-Met-Asp-Asp (YMDD). This motif is essential for nucleotide binding and for polymerase activity, and mutations in this region may confer resistance to lamivudine and thus have important therapeutic and prognostic implications. Pooled data from three clinical trials involving 731 treatment-naïve patients who received lamivudine (100 mg/day) for 1 year demonstrated that HBeAg seroconversion (defined as loss of HBeAg, detection of anti-HBe, and loss of HBV DNA) occurred in 16% to 18% of patients compared with as few as 6% of untreated controls.<sup>125,126</sup> Follow-up reports of the Asian study on lamivudine showed that the HBeAg seroconversion rates increased with time, from 17% at 1 year to 27%, 33%, and 47% at 2, 3, and 4 years, respectively.<sup>127</sup>

However, the selection of lamivudine-resistant mutants during therapy is a major concern. The most common mutation affects the YMDD motif of the HBV DNA polymerase (methionine to valine or isoleucine). Lamivudine resistance is usually manifested by the reappearance of HBV DNA in serum after its initial disappearance. In the Asian study, lamivudine resistance increased from 14% at 1 year to 38%, 49%, and 66% after 2, 3, and 4 years of treatment, respectively.<sup>127</sup> However, HBeAg seroconversion has been maintained in 25% of patients who continued treatment after the detection of mutants.<sup>128</sup> Dienstag and colleagues studied histologic and clinical outcome after 3 years of lamivudine therapy in 63 patients who received 100 mg daily.<sup>129</sup> Most patients showed improvement (56%) or no change (33%) in the necroinflammatory score compared with baseline (median follow-up, 3.5 years). The proportion of patients showing histologic improvement overall was higher in the subgroup of subjects without YMDD mutation compared with the group with the YMDD variant, but even in the latter group there were patients whose histologic activity scores decreased. Five patients showed improvement of cirrhosis by the end of treatment, and one reverted almost completely. The authors concluded that although the emergence of YMDD mutations can diminish histologic benefit, these patients do not experience rapid deterioration and instead benefit from continued treatment.

Durability of response after HBeAg seroconversion with lamivudine treatment is variable. HBeAg seroconversion durability is reported in 77% of western patients<sup>130</sup> after 3 years, in contrast with a much lower response in Asian studies.<sup>131,132</sup> A study in Taiwan conducted on 82 HBeAg-positive patients with chronic hepatitis on liver biopsy showed a sustained response (seroconversion of HBeAg to anti-HBe, clearance of HBV DNA, and normalization of ALT for 1 year after 12 months of lamivudine therapy) in 52% of patients.<sup>133</sup> Patients with genotype B had a much higher rate of sustained response than those with genotype C (61% vs. 25%, respectively).

Lamivudine should be administered for at least 1 year,<sup>122</sup> but the benefit of prolonged therapy should be balanced against the risk of resistant mutants. The recommended dose for adults is 100 mg daily, and it should be reduced in patients with renal insufficiency. Two thirds of patients with HBeAg-negative chronic HBV infection can achieve an initial

response (clearance of HBV DNA)<sup>134</sup>; however, the relapse rate after stopping therapy is even higher than with IFN treatment in this particular group of patients.<sup>135</sup> The incidence of YMDD mutants in HBeAg-negative patients increases with time, as occurs in HBeAg-positive chronic hepatitis B.<sup>134</sup>

Lamivudine is well tolerated in patients with decompensated cirrhosis and may even result in clinical improvement and reduction of the Child-Pugh score.<sup>136–138</sup> However, the potential selection of lamivudine-resistant mutations might be a drawback for prolonged therapy in patients with cirrhosis undergoing orthotopic liver transplantation.<sup>139</sup> Lok and coworkers<sup>140</sup> analyzed retrospectively data for nearly 1000 patients from clinical trials performed on all five continents among HBeAg-positive subjects with chronic hepatitis B who were treated with lamivudine for up to 6 years. This cohort was compared with a group of 200 patients who received placebo for 1 year. The median duration of lamivudine treatment was 4 years. The most common adverse events were hepatitis flares occurring in 21% of patients receiving lamivudine in year 5, most of them related to HBeAg seroconversion and emergence of lamivudine-resistant mutations, but overall fewer than 1% had liver-related adverse side effects or decompensation. Patients who had lamivudine-resistant mutants for more than 4 years tended to have more adverse events, leading these experts to suggest that HBeAg-positive patients with compensated liver disease may remain stable during the first 1 to 3 years after the emergence of lamivudine-resistant mutations, but more prolonged therapy may be associated with clinical worsening. The emergence of lamivudine-resistant mutations signals the time when alternative treatments for chronic hepatitis B should be contemplated.

### Adefovir Dipivoxil

Adefovir dipivoxil, an antiviral drug recently approved by FDA for the therapy of chronic hepatitis B, is an oral prodrug of adefovir, an analog of adenosine monophosphate. Adefovir diphosphate, the active metabolite, effectively inhibits HBV DNA polymerase intracellularly. Marcellin and colleagues<sup>141</sup> conducted a study on 515 HBeAg-positive patients with chronic hepatitis B receiving adefovir dipivoxil 10 mg/day, 30 mg/day, or placebo for 48 weeks. Histologic improvement, HBeAg seroconversion, normalization of ALT, and clearance of HBV DNA were observed in a much higher proportion of adefovir dipivoxil-treated patients compared with those who received placebo. The safety profile of the 10 mg dose was similar to that of placebo, whereas the 30 mg dose was associated with a higher frequency of adverse events and renal function abnormalities. No adefovir-resistant mutants were identified in the HBV DNA polymerase gene. Hadziyannis and colleagues studied the impact of adefovir dipivoxil in 185 patients with HBeAg-negative chronic hepatitis B in a multicenter, double-blind, placebo-controlled trial.<sup>142</sup> Patients received adefovir dipivoxil 10 mg daily or placebo for 48 weeks. Fifty-one percent of patients in the adefovir dipivoxil group reduced their HBV DNA levels to fewer than 400 copies per milliliter, compared with 0 patients in the placebo group. Histologic improvement and normalization in ALT levels were significantly more frequent in the adefovir dipivoxil group. No mutations in the HBV DNA polymerase associated with resistance to the drug were observed. The absence of adefovir-resistant mutations in

the two trials was confirmed in a sophisticated virologic substudy conducted by Westland and associates.<sup>143</sup> However, Angus and colleagues reported the first case of the occurrence of both virologic and clinical resistance to adefovir dipivoxil therapy in a patient who developed breakthrough during a 96-week course of adefovir dipivoxil.<sup>144</sup> Comparing pretreatment and post-treatment HBV DNA by PCR sequencing, an asparagine to threonine mutation was identified at residue 236 in domain D of the HBV polymerase, causing a marked reduction in the susceptibility to adefovir. The patient responded to lamivudine “rescue” therapy, achieving normalization of ALT and significant decrease in HBV DNA. Despite data suggesting that resistance to adefovir dipivoxil is significantly less common than for lamivudine, the clinician treating patients with chronic hepatitis B should take into consideration the fact that drug resistance is likely to emerge to any antiviral drug during prolonged monotherapy.<sup>141</sup> In the near future, combination antiviral therapy may provide the best chance of long-term suppression of viral replication and prevention of disease progression.<sup>145</sup> Combination therapy with lamivudine and adefovir dipivoxil has recently been proved safe and effective in both compensated and decompensated patients with chronic hepatitis B in two well-designed, randomized clinical trials.<sup>146,147</sup>

### Other Antiviral Agents

Entecavir is a deoxyguanine nucleoside analog. It is a selective inhibitor of the replication of HBV, capable of causing pronounced reduction in HBV DNA levels in short-term studies<sup>148</sup> with almost no side effects. Long-term clinical trials are needed to establish the efficacy of this antiviral agent.

Famciclovir is the oral prodrug of penciclovir. It is less efficacious than lamivudine, and famciclovir-resistant mutants have been reported.<sup>149</sup> It has to be administered three times a day. For these reasons, it seems unlikely that famciclovir will be part of the therapeutic regimes against chronic hepatitis B.<sup>122</sup>

### PREVENTION AND CONTROL

The initial strategy for vaccination against hepatitis B was targeted against high-risk groups such as sexual and close contacts of patients with hepatitis B, homosexual men, infants born to infected mothers, IVDUs, hemodialysis patients, sexually active heterosexuals, and health care personnel. However, this strategy failed to have a significant impact on the disease prevalence and incidence because many of these individuals were infected with HBV before vaccination.<sup>66</sup> Since about 30% of all cases of acute hepatitis B occur in persons who do not have an identifiable risk factor, control of hepatitis B in western societies requires routine screening of all pregnant women and routine immunization of all infants,<sup>2,66</sup> which would lead to disease prevention by providing immunity before persons engage in high-risk activities. For these reasons, it is now recommended to incorporate hepatitis B immunization into the standard childhood vaccination programs (see later discussion). Control in less developed regions rests on infant immunization. The original plasma-derived vaccine (Heptavax-B), widely used among health care workers and other high-risk groups in the early 1980s,<sup>150</sup> is no longer being manufactured in the United States. Two vaccines produced by recombinant DNA technology,

\*New pediatric formulation.

†Special formulation.

‡Two 1-mL doses administered at one site at 0, 1, 2, and 6 months.

Recombivax-HB and Engerix-B, are currently available. The doses and recommended schedules are shown in Table 64-5. The adult vaccination schedule is a series of three doses given by IM injection in the deltoid muscle at 0, 1, and 6 months. Engerix-B is now licensed for use on a four-dose schedule with doses at 0, 1, 2, and 12 months. For adult patients lacking antibodies against hepatitis A, Twinrix is a suitable alternative (see Prevention and Control for hepatitis A virus).

A rapid immunization schedule using Engerix-B given at 0, 1, and 2 months was compared with the standard schedule (0, 1, and 6 months) in a prospective, randomized fashion.<sup>151</sup> The accelerated schedule provided seroconversion rates identical to those offered by the standard schedule. The importance of vaccination among health care workers cannot be over-emphasized and is well exemplified in a report describing the transmission of HBV from an unvaccinated thoracic surgeon to 19 patients in 1 year.<sup>152</sup> Protection lasts at least as long as measurable antibody to HBsAg (anti-HBs) persists in the circulation.<sup>122</sup> Five years after vaccination, about 80% of vaccinated persons have antibody levels considered protective ( $\geq 10$  mIU/mL).<sup>153</sup> The Advisory Committee for Immunization Practices (ACIP) and the American Academy of Pediatrics currently recommend that all infants be vaccinated against HBV.<sup>122</sup> There are two dosing options: (1) at birth, 1 to 2 months of age, and 6 to 18 months of age; or (2) 1 to 2 months of age, 4 months, and 6 to 18 months. The loss of detectable anti-HBs after vaccination does not necessarily mean a lack of protection. Intact immunologic memory B cells may persist in hepatitis B vaccine responders who have low ( $<10$  mIU/mL) anti-HBs levels 7 to 8 years after immunization.<sup>154</sup> A European Consensus Group on hepatitis B immunity noted that there are no data to support the need for booster doses in immunocompetent individuals responding to a primary course.<sup>155</sup> Patients undergoing hemodialysis represent a special group, since their response rate to hepatitis B vaccine is only around 60%, and hepatitis B can occur even in patients thought to have an antibody

response to the vaccine.<sup>156</sup> Hemodialysis patients represent the only group in which booster immunization is recommended when anti-HBs levels fall below 10 mIU/mL.<sup>157</sup> Other immunocompromised patients such as organ transplant recipients also have a low response rate to hepatitis B vaccination.<sup>158</sup> Among native residents in areas endemic for HBV such as the Peruvian Amazonian region, the response rate after the administration of three doses of Engerix-B was 73.5%.<sup>159</sup> In this study, the third dose was administered 14 months after the first in 16% of the natives, with no difference in the rate of seroconversion when compared with the 32% that received the recommended 0, 1, and 6 months regimen. This has practical implications for vaccination programs in rural areas of difficult access, where flexibility in the vaccination schedule is required.

Reports of multiple sclerosis following HBV vaccination caused concern regarding the safety of this vaccine. However, a large case-control study performed in nurses from the United States showed no association between HBV vaccination and this neurologic disease.<sup>160</sup> A recombinant vaccine, Hepacare, contains pre-S1 and pre-S2 antigens in addition to HBsAg and appears to provide equivalent seroprotection to a standard three-dose regimen with Engerix-B within 6 months.<sup>161</sup> It has been suggested that the inclusion of the pre-S antigens in this novel vaccine may enhance its immunogenicity and possibly offer advantages for adults at risk for suboptimal serologic response to conventional recombinant vaccines, such as older adults or immunosuppressed persons.<sup>162</sup>

Postexposure prophylaxis is indicated in unvaccinated persons who are exposed to HBV. Infants born to HBsAg-positive mothers should receive hepatitis B immunoglobulin (HBIG) 0.5 mL IM and hepatitis B vaccine within 12 hours of birth and two more doses of vaccine at 1 and 6 months of age. For sexual contacts, HBIG 0.06 mL/kg IM within 2 weeks of exposure and simultaneous hepatitis B vaccination series are recommended.<sup>122</sup> The HBV vaccine and HBIG should be administered at different sites. If the exposed person has previously been vaccinated against HBV, serum anti-HBs titers should be determined

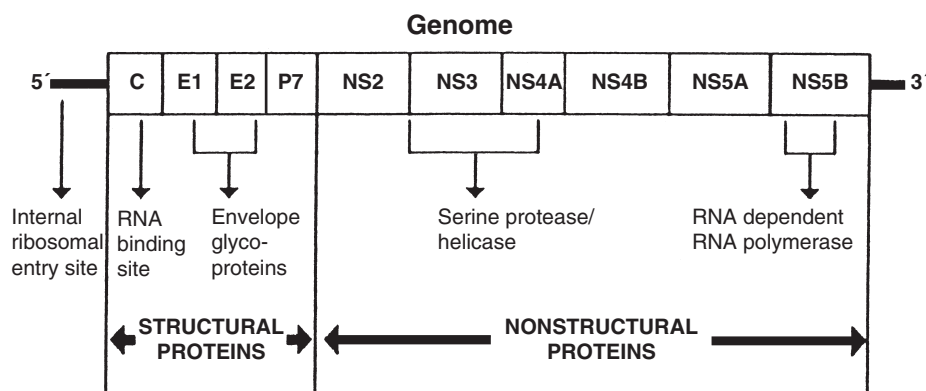

immediately, and a new vaccine series is recommended for individuals with antibody levels less than 10 mIU/mL. Health care workers who have a percutaneous exposure should follow the same guidelines as patients exposed by sexual contact. General guidelines for hepatitis B prophylaxis after percutaneous or mucosal exposure are shown in Table 64-6.

## ■ Hepatitis C

When stored samples of prospectively studied cases of transfusion-associated hepatitis in 1975 revealed that most cases were not associated with hepatitis A or B viruses, the term “non-A, non-B” (NANB) hepatitis was adopted.<sup>163</sup> The infectious nature of NANB hepatitis was demonstrated a few years later when it was transmitted to chimpanzees, and in 1989 a short segment of the viral RNA was reverse-transcribed, cloned, and sequenced, identifying the agent, which was named hepatitis C virus (HCV).<sup>164</sup>

### AGENT

HCV is a single-stranded RNA virus with a genome length of approximately 9.5 kb and a mean diameter of approximately 55 nm, classified in the family approximately Flaviviridae (with yellow fever, dengue, and Japanese encephalitis viruses), and is the only member of the genus *Hepacivirus*. The genome of HCV (Fig. 64-7) contains a single large open reading frame (ORF) with an upstream 5′ nontranslated region that plays a role in translation of the viral proteins and replication of the viral RNA. The ORF encodes a large polyprotein that is cleaved into structural and nonstructural proteins by host and virus proteases.<sup>165</sup> Approximately 30% of the ORF adjacent to the 5′ end encodes the structural proteins which include the nucleocapsid protein, core (C), with RNA binding activity, two envelope proteins, E1 and E2, and possibly a small “viroporin,” p7, that forms an ion channel in membranes.

**FIGURE 64-7** Hepatitis C genome. (From Koff RS, Dienstag JL, Riely CA, et al: AGA Clinical Teaching Project, Unit 3, Viral Hepatitis, 2nd ed. Timonium, Md., Milner-Fenwick, 1994.)

The 5' nontranslated RNA (NTR) acts as an internal ribosome entry site (IRES), and its structure has been visualized by cryoelectron microscopy.<sup>166</sup> The nonstructural proteins are involved in polyprotein processing and viral RNA replication and include two viral proteases (activities associated with NS2/NS3 and NS3/4A) and an RNA-dependent RNA polymerase (NS5B) adjacent to the 3' end. NS3 has both helicase and protease activity. Six distinct genotypes of HCV have been identified. There appear to be differences among genotypes regarding virulence, geographic distribution, and response to therapy with IFN. HCV is characterized by its genetic variability, undergoing a high rate of mutation.<sup>167</sup> These mutations are more frequently identified in the hypervariable region of the genome, located in the E2 region. An infected individual typically has multiple related HCV-RNA sequences in the blood and liver simultaneously, termed *quasispecies*.<sup>168</sup> These arise as a result of the tendency of the viral polymerase to be error-prone and because of multiple selective forces including immune pressure exerted by the host. This concept may explain in part the enormous difficulties encountered in efforts to develop an effective vaccine against HCV. The 5'NTR is highly conserved, however, and is utilized in the detection of HCV-RNA by the reverse transcriptase-PCR (RT-PCR) method.

## EPIDEMIOLOGY

The worldwide prevalence of HCV infection, based on immunoassays for antibodies to HCV (anti-HCV), approximates 1% to 2%.<sup>169</sup> In the United States, 1.8% of the population is positive for anti-HCV antibodies.<sup>169</sup> Seroprevalence using second-generation assays is around 0.3% in Australia; 1.5% to 3% in the Philippines, Indonesia, Thailand, and Vietnam; 1% in Taiwan and China; and as high as 3% to 4% in Japan.<sup>170</sup> The prevalence is approximately 7% in sub-Saharan Africa,<sup>171</sup> and the highest reported prevalence is in Egypt, where 6% to 28% (average, 22%) have antibodies against HCV, presumably owing to spread by contaminated needles during parenteral antischistosomal treatment.<sup>172</sup> The prevalent genotype in Europe is 1b (47%), followed by 1a (17%) and 3 (16%).<sup>173</sup> In the United States, about 57% of cases have genotype 1a, 17% genotype 1b, 14% genotype 2, and 7% genotype 3.<sup>174</sup> The great majority of hemophiliacs who received blood products during the 1980s became infected with HCV.<sup>175</sup>

The risk of acquiring HCV from a blood transfusion in the United States was previously about 1 in 103,000 transfused units,<sup>176</sup> probably due to blood donations in the 12-week period before development of anti-HCV in the infected donor. This interval may be shortened to 3 weeks using RT-PCR to detect HCV RNA.<sup>177</sup>

HCV infection is also common among IVDUs, acquired by sharing contaminated needles. The prevalence of anti-HCV in this population ranges from 50% to 90%.<sup>178,179</sup> In other areas of the world, the intravenous route is also important, with a prevalence of HCV among IVDUs around 70% in New Zealand, Hong Kong, and Taiwan.

Transmission of HCV to health care workers by needle sticks is well documented,<sup>180,181</sup> and the 2% to 4% seroconversion rate reported after percutaneous accidental exposure falls between the 15% to 30% risk for HBV and the 0.3% for human immunodeficiency virus (HIV).<sup>182,183</sup> However, using RT-PCR for the detection of HCV-RNA, Mitsui and colleagues reported a rate of 10% following a single accidental percutaneous exposure.<sup>181</sup> Cardiothoracic surgery is associated with a high risk of glove perforation occurring during wire sternotomy closure,<sup>182</sup> leading to contact of the surgeon's blood with the patient's open wound. Hepatitis C has been transmitted nosocomially during colonoscopy or general surgery, although such infections appear to be unusual.<sup>182,184</sup> Health care workers are usually at much greater risk of infection from their patients than vice versa. Patients on chronic hemodialysis are considered a high-risk population, and studies using RT-PCR for the detection of HCV-RNA show a high prevalence of HCV among these patients, which can be underestimated when only anti-HCV tests are utilized.<sup>185</sup>

Perinatal transmission of HCV is uncommon. HCV-RNA detection is preferable to antibody detection methods,<sup>186</sup> since the passive acquisition of maternal anti-HCV has been found in 72% to 86% of infants, which is lost between the second and twelfth months after birth.<sup>187</sup> The risk of transmission of HCV from mother to infant is increased if the mother is coinfecting with HIV.<sup>188,189</sup> A hypothetical explanation for this phenomenon is the high HCV titers in these mothers as a consequence of HIV-related immunosuppression.<sup>187</sup> The likelihood of sexual transmission of HCV is similarly low although not negligible.<sup>190</sup> In a study of Japanese sex workers, the prevalence of HCV was 6.2%,<sup>191</sup> significantly higher than in the general population.

### Hepatitis C

#### Anti-HCV Prevalence

- >5%—High
- 1.1%-5%—Intermediate
- 0.2%-1%—Low
- ≤0.1%—Very Low
- Unknown

The incidence of anti-HCV antibodies is only minimally increased in male homosexuals, in comparison to the high prevalence of HBV and HIV infection. Wright and colleagues retrospectively evaluated more than 500 HIV-positive male homosexuals without a history of blood transfusion or IV drug use and found that the prevalence of anti-HCV as determined by second-generation antibody testing was 11.7%, several times higher than the rate reported in volunteer blood donors.<sup>192</sup> Among stable heterosexual partners of HCV-infected, HIV-negative persons, the median rate of anti-HCV positivity is 1% in North America, 6% in southern Europe, and 11% in Southeast Asia.<sup>193</sup> Importantly, the use of genotyping to evaluate anti-HCV concordant couples may lead to overestimation of HCV sexual transmission, since HCV genotypes that are prevalent in the population may be present in partners with different sources of infection. Rather, sequence analysis should be used for this purpose.<sup>193</sup>

### DISEASE

The clinical presentation of acute HCV infection is indistinguishable from other acute viral hepatitis. The incubation period averages about 6 weeks, based on transfusion-related acquired acute cases,<sup>194</sup> which is intermediate between that for hepatitis A and hepatitis B. Symptoms are usually very mild, characterized by malaise and fever and with elevations of aminotransferase activity that are usually less pronounced

than in hepatitis B. Acute hepatitis C accounts for around 16% of cases of acute hepatitis in the United States.<sup>195</sup> The vast majority of cases has an anicteric course and may go unnoticed if laboratory tests are not monitored. Although some investigators have found cases of fulminant hepatitis and the presence of HCV in blood,<sup>196,197</sup> there is little evidence that HCV has a fulminant course in the United States, although this has been more commonly reported in Japan.

Probably the most remarkable aspect of HCV infection from a clinical standpoint is its ability to become chronic, as occurs in more than 50% to 85% of patients.<sup>198</sup> A Japanese study of the natural history of HCV disease suggests that approximately 20 years are required to develop cirrhosis, and 30 years for hepatocellular carcinoma, but some cases appear to extend over a 60-year period.<sup>199</sup> Once HCV infection is established, chronicity is the rule, and histologic progression evolves insidiously. However, many patients remain without significant liver disease for decades or even for life. The rate of progression of fibrosis seems to be related to the age of acquisition of the infection. Children seem to be more likely to clear the infection spontaneously than adults, for unknown reasons.<sup>200,201</sup> Factors accelerating the progression to fibrosis include alcohol, male sex, advanced age at acquisition, smoking, and coinfection with HIV or HBV.<sup>202-206</sup> Community-based cohort studies are more accurate than post-transfusion cohorts, blood banks, or liver clinics for estimating disease progression at a population level because they avoid selection bias.

The estimated rate of progression to cirrhosis after 20 years of chronic HCV infection is between 4% and 10% in community-based cohorts.<sup>207</sup>

As a rule, clinically apparent disease is uncommon, and patients often come in late in the course of the disease with manifestations of end-stage liver disease. A large proportion of cases of chronic hepatitis C are identified incidentally during biochemical screening at routine examinations or in the course of screening for blood donation. Patients with chronic HCV infection typically have nonspecific symptoms such as fatigue and malaise. Serum alanine aminotransferase (ALT) levels fluctuate and may even be normal, making ALT an unreliable marker of disease activity or recovery. Many extrahepatic manifestations have been associated with chronic HCV infections. Essential mixed cryoglobulinemia is characterized by circulating mixed cryoprecipitable globulins and can be accompanied by arthritis, generalized vasculitis, and cutaneous purpura.<sup>208</sup> Successful interferon treatment is associated with a decrease in “cryocrit” and improvement in the clinical manifestations of essential mixed cryoglobulinemia.<sup>209</sup> Porphyria cutanea tarda (PCT) is characterized by the development of skin hypersensitivity to sun, formation of vesicles and bullae, hyperpigmentation, and hypertrichosis, associated with iron overload and chronic liver disease.<sup>209</sup> Anti-HCV was found in 82% of Italian patients and in 79% of Spanish patients with PCT by second-generation immunoassays.<sup>210,211</sup>

A subset of HCV-infected patients may have membranoproliferative glomerulonephritis as a consequence of deposition of HCV antigen-antibody complexes in glomeruli.<sup>212</sup> Proteinuria and glomerular deposition of IgG, IgM, and C3 have been demonstrated, as well as HCV-RNA-containing cryoprecipitates and antibodies to nucleocapsid proteins. Lymphocytic sialoadenitis and capillaritis are frequent findings in salivary gland and labial mucosal biopsy specimens, resembling those seen in Sjögren’s syndrome.<sup>213,214</sup> Other extrahepatic manifestations of HCV include corneal ulcers,<sup>215</sup> erythema nodosum,<sup>216</sup> and polyarteritis nodosa.<sup>217</sup> HCV RNA has been detected in peripheral lymphocytes and in biopsy samples of lymphoma tissue, although its significance is uncertain.<sup>218</sup> Gisbert and colleagues published a meta-analysis evaluating the prevalence of hepatitis C infection in patients with B-cell non-Hodgkin lymphoma (NHL).<sup>219</sup> They found a prevalence of HCV in patients with NHL of 15%, higher than that reported in the general population.

A significant proportion of patients with HCC have HCV infection, detected not only by anti-HCV tests but also by HCV-RNA levels.<sup>220,221</sup> Time elapsed since acquiring HCV infection and the development of cirrhosis seems to be the main factor for the development of HCC. A median of 30 years is the time frame in which most HCC begins to appear.<sup>222</sup> The strongest correlation between the presence of HCV infection and HCC is seen in Japan, Spain, and Italy, while HCV is less commonly found in patients with HCC in the United States and southern Africa.<sup>223,224</sup> HCV was present in 26% of 1930 patients with HCC in the absence of HBV markers.<sup>225</sup> In the United States, there was a twofold increase in HCC between 1975 and 1998, and a shift in incidence from elderly patients to relatively younger patients between 40 and 60 years of age has been observed.<sup>222</sup>

Despite the strong epidemiologic association between HCV and HCC, little is known about the mechanism by

which chronic hepatitis C results in HCC. Although HCC has been described in noncirrhotic livers,<sup>226</sup> cirrhosis is present in the majority of patients with HCV-related HCC. There is no evidence that the HCV genome can become integrated within the genome of the hepatocytes as occurs in chronic HBV infection.<sup>227</sup> However, transgenic mice expressing HCV proteins (core protein or the entire polyprotein) have been shown to be at risk for HCC despite the absence of inflammation or cirrhosis in these animals. As with HBV-associated HCC, chronic inflammation, oxidative stress, and attendant host chromosomal DNA damage may all contribute to carcinogenesis.

## **PATHOGENESIS AND IMMUNITY**

Recent depletion experiments in chimpanzees have defined important roles for both CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes in protection against HCV infection but have not resolved longstanding questions concerning the mechanisms exploited by the virus in establishing persistent infections. HCV-specific CD4<sup>+</sup> T cells are detected both in the liver and peripheral blood of HCV-infected patients.<sup>228</sup> The CD4<sup>+</sup> T cell response to HCV is sustained and vigorous in patients with acute, self-limited HCV infection, and is weak and delayed in patients who become chronically infected.<sup>229</sup> The potential protective role of HCV-specific CD4 T cells is suggested by studies showing accelerated liver disease progression in patients co-infected with HIV, who have generalized impairment in CD4<sup>+</sup> T cells.<sup>230</sup> CD4<sup>+</sup> T cell help is required for the development of an effective CD8<sup>+</sup> response, and it has been suggested that interferon- $\gamma$ -secreting CD8<sup>+</sup> T cells play an important role in clearance of the virus from liver. However, the CD8<sup>+</sup> T-cell response in HCV infection demonstrates several puzzling features. HCV-specific CD8<sup>+</sup> T cells are present and activated within the liver in patients with chronic hepatitis C, but they are incapable of eliminating the infection. In some patients, they appear to have a “stunned” phenotype, and do not secrete interferon- $\gamma$  in response to antigen stimulation. The HCV-specific CD8<sup>+</sup> T-cell response is remarkably variable, and more work is needed to characterize these responses in chronic HCV infection.<sup>231</sup>

It appears that the antibody response is of limited importance in clearing HCV. Two studies seem to exclude a critical role for antibodies in the resolution of infection.<sup>232,233</sup> However, more studies are needed to define the role of antibody in immunity. The quasispecies nature of the virus confers a survival advantage, allowing rapid selection of mutants that are capable of escaping antibody-mediated neutralization.<sup>234</sup>

Finally, recent evidence suggests that HCV is capable of disrupting important innate immune responses that not only have direct intracellular antiviral effects but also play a role in shaping subsequent adaptive T-cell immunity. The NS3/4A protease acts to disrupt the signaling pathways that lead to induction of endogenous interferon synthesis in response to virus infection, by blocking the virus-induced activation of interferon-regulatory factor 3 (IRF-3).<sup>235,236</sup> Moreover, the NS5A protein appears to block one of the interferon-mediated effector mechanisms by binding to protein kinase R (PKR) near its catalytic site, and preventing the dsRNA-activated PKR-mediated shutdown of viral and cellular protein translation.<sup>237</sup> The disruption of innate immune responses to the infection may thus be very important in determining persistence of the

infection, while also perhaps contributing to resistance to interferon therapy.

## DIAGNOSIS

### Indirect Tests: Antibody Assays

The detection of anti-HCV antibodies is the most common and practical means of diagnosing HCV infection. Second- or third-generation enzyme immunoassays (EIAs) are used to detect mixtures of antibodies against various HCV epitopes of the core, NS3, NS4, and (in third-generation assays) NS5 proteins.<sup>238</sup> Current EIAs have a specificity of 99% and are positive in more than 99% of immunocompetent patients with detectable HCV RNA.<sup>239</sup> EIAs can be negative in hemodialysis patients or in profoundly immunodepressed patients. The presence of elevated aminotransferases in a patient with EIA-positive anti-HCV is almost diagnostic of active HCV infection, although in some cases it requires confirmation with molecular HCV RNA detection. Immunoblot (RIBA) tests have been used as confirmatory tests, but currently there is no role for them in the clinical setting except for the low-risk patient who tests positive for anti-HCV and has negative HCV RNA.<sup>238</sup>

### Direct Tests

#### Detection of HCV RNA

Qualitative HCV RNA detection assays are useful because they are much more sensitive than quantitative assays. They are based on target amplification, by either RT-PCR or transcription-mediated amplification (TMA).<sup>240</sup> The World Health Organization (WHO) has established an international standard for HCV RNA units.<sup>241</sup> One international unit (IU) represents a certain amount of HCV RNA rather than the number of viral particles (copies per milliliter); this standard should be universally adopted. The detection cutoff of the two commercially available assays is 50 IU of HCV RNA per milliliter. The manual TMA assay is more sensitive (10 IU/mL), but both assays are 98% to 99% specific.<sup>240</sup> For quantification of HCV RNA, the detection limits of current assays vary from 30 IU/mL to 615 IU/mL, and the upper limit of linear quantification is between 500,000 IU/mL and 7,700,000 IU/mL. Samples above the upper limit of normal must be diluted 1/10 or 1/100 and have a specificity of 98% to 99%.<sup>240</sup> Three commercial tests are currently available to quantify HCV viremia: a branched-chain DNA assay (Quantiplex HCV RNA, version 2.0) and two assays involving RT-PCR (Cobas Amplicor HCV monitor, version 2.0 and HCV Superquant). All are reliable although not easily comparable.<sup>242</sup> Future assays will be predominantly real-time RT-PCR.

Even with the most sensitive technique, however, HCV-RNA may be sporadically undetectable in serum, and a single negative HCV-RNA determination should not be interpreted as absolute evidence of absence of HCV infection.

### HCV Core Antigen

Total HCV core antigen can be detected and quantified with an EIA assay. The HCV core antigen correlates closely with the HCV RNA level<sup>243</sup>; however, the assay does not

detect HCV core antigen when the HCV RNA level is below 20,000 IU/mL.

## Clinical Applications

HCV RNA positivity in an anti-HCV-negative patient is highly suggestive of acute hepatitis C. Subjects with anti-HCV antibodies but with no HCV RNA may have cleared HCV RNA spontaneously in the past.<sup>238</sup> It is advisable to test such patients for HCV RNA a few months later, since HCV RNA levels may fluctuate somewhat. Symptomatic patients with both anti-HCV and HCV RNA may have acute hepatitis C or exacerbation of chronic hepatitis C. HCV RNA becomes detectable in serum between 1 and 2 weeks following occupational exposure. It is recommended that the source and the exposed individual be tested for antibody to HCV RNA. If the source individual is HCV EIA-positive, HCV RNA, anti-HCV, and ALT should be tested in the exposed individual at exposure and again between 2 and 8 weeks later. If seroconversion occurs, the exposed individual should be referred to a specialist for consideration of therapy, as early treatment with IFN may be efficacious in this setting (see later discussion). Infants born to HCV-positive mothers should be tested for HCV infection by HCV RNA tests on two occasions between the ages of 2 and 6 months or be tested for anti-HCV after 15 months, since passive transplacental transfer of antibodies from the mother may be present.<sup>244</sup>

### Liver Biopsy

Testing for ALT is not accurate in determining the severity of liver disease. The levels may be normal or fluctuate, and a single normal value does not rule out active infection, advanced disease, or cirrhosis<sup>169</sup> (Fig. 64-8). Liver biopsy is frequently recommended in the initial evaluation of patients with chronic hepatitis C with abnormal levels of ALT.<sup>245</sup> The typical histologic findings in chronic hepatitis C include hepatocellular necrosis and inflammation (grade) and fibrosis (stage).<sup>246</sup> Assessment of the stage and rapidity of progression of fibrosis is helpful in determining the prognosis and need for therapy in an individual patient. Liver biopsy is the gold standard to assess fibrosis. The most frequently used staging

**FIGURE 64-8** Dense periportal lymphomononuclear infiltrate with interphase hepatitis is seen.

systems are the Histologic Activity Index (HAI or Knodell Score) and the METAVIR.<sup>247</sup> These scoring systems have potential limitations. Hepatic fibrosis may not be homogeneous throughout the liver, and in some cases fibrosis may be underestimated and cirrhosis missed. There are no clinical, biochemical, or virologic tests to accurately predict progression of fibrosis.<sup>248</sup> Patients with minimal or no fibrosis can be assured of a favorable outcome and even defer antiviral therapy.<sup>245</sup> Additionally, liver biopsy can provide information regarding the contribution of iron, concurrent alcohol use, and steatosis. There is a significant association between steatosis and inflammation and fibrosis score on liver biopsy.<sup>249,250</sup> Genotype 3a is consistently linked to steatosis more strongly than other genotypes.<sup>250</sup> Accumulating evidence suggests that steatosis contributes to the progression in HCV-related disease, probably owing to oxidative stress and cytokine-mediated injury.<sup>251</sup> Because a favorable response to antiviral therapy occurs in 80% of patients infected with genotype 2 or 3, it may not be always necessary to perform liver biopsy in these patients to make a decision to treat.<sup>245</sup>

## TREATMENT AND PROGNOSIS

Since a large proportion of patients with chronic HCV infection develop progressive chronic hepatitis, cirrhosis, and sometimes HCC, the main rationale for treatment of chronic hepatitis C is to prevent these complications, render the patient noninfectious, and eventually ameliorate the symptoms. The decision to treat patients should be based on solid diagnostic grounds, ideally with histologic evaluation.

In 1991, recombinant IFN- $\alpha$  was approved for the treatment of patients with chronic hepatitis C with persistently elevated serum aminotransferases and biopsy-proved chronic active hepatitis. Two important preliminary trials published in 1989,<sup>252,253</sup> which involved the administration of IFN to patients with chronic HCV infection, showed complete biochemical resolution in roughly 50% of patients, with simultaneous histologic improvement after 6 months of therapy. Aminotransferases were at baseline levels in nearly 50% of responders 1 year after discontinuation of therapy. The success of clinical trials has been evaluated in terms of response (i.e., clearance of HCV RNA) at the end of therapy (*end of treatment response*, *ETR*), and 6 months after cessation of therapy (*sustained virologic response*, *SVR*). Long-term follow up of patients with SVR shows a high probability of maintaining virologic and histologic remission over the years.<sup>254</sup> The patient with acute hepatitis C represents a special and controversial situation regarding therapy. Jaeckel and associates<sup>255</sup> treated 44 acutely infected patients with a 24-week course of IFN- $\alpha$  monotherapy, and 98% achieved a sustained biochemical and virologic response. More recently, Gerlach and coworkers<sup>256</sup> identified 60 individuals with acute hepatitis C as part of a prospective observational study investigating the outcome of the natural course of infection in patients with acute hepatitis C. Six patients received immediate antiviral therapy, and 54 were left untreated. Of the 37 (68%) of 54 patients who initially cleared virus spontaneously, 13 relapsed and remained virus-positive, while 24 (44%) remained persistently virus-negative. Those with self-limited disease were more likely to have symptomatic onset of illness, whereas no patient with asymptomatic presentation cleared HCV RNA without treatment.

Importantly, antiviral therapy was begun 3 to 6 months after onset of symptoms, and in 21 (81%) of 26 a sustained response was achieved. Therefore, this and other studies<sup>257</sup> support the concept that a significant proportion of patients with acute hepatitis C will clear virus spontaneously and not require immediate therapy. A prudent period of observation with serial viral load determinations following acute symptomatic hepatitis C infection is a reasonable management strategy for this subgroup.

Regarding chronic hepatitis C, only a subgroup of patients have a clear indication for therapy. Patients with detectable HCV RNA, persistently elevated ALT, and moderate necrosis, inflammation, and fibrosis on liver biopsy should be offered therapy if there are no contraindications, since they are at high risk for disease progression.<sup>245,258</sup> Patients with normal or near-normal ALT, or no fibrosis and minimal necroinflammatory changes on liver biopsy, may not need treatment and should be monitored periodically,<sup>245</sup> but decisions to treat such patients should be carefully individualized, and the patient's desire to eliminate the virus should be considered. Several variables have been consistently associated with a higher likelihood of SVR in different clinical trials: HCV genotype other than 1, lower baseline viral load, absence of bridging necrosis/cirrhosis, low body mass, female sex, and adherence to the regimen.<sup>259–265</sup> Persons with decompensated cirrhosis are unlikely to have a response and may deteriorate with therapy.

Monotherapy with IFN shows an SVR of less than 20%, but the addition of ribavirin to IFN improves the SVR to 44%.<sup>259,260</sup> The attachment of polyethylene glycol to IFN- $\alpha$  (pegylated IFN, PEG IFN) extends the half-life and duration of therapeutic action of IFN- $\alpha$ . In contrast to IFN- $\alpha$ , which is administered three times a week, PEG IFN is given only once a week. Two PEG IFN formulations are currently available for use as once weekly therapy for hepatitis C: 40 kD PEG chain form of IFN- $\alpha$ -2a and 12 kD chain form of IFN- $\alpha$ -2b. The former is supplied as a ready-to-use formulation, independent of body weight, whereas the latter is supplied as a lyophilized powder that requires reconstitution before use and is formulated by body weight, expressed in  $\mu\text{g}/\text{kg}/\text{wk}$ . The former is cleared primarily by the liver, whereas 30% of the PEG IFN- $\alpha$ -2b is cleared by the kidney. Clinical trials comparing PEG IFN monotherapy to standard IFN have been performed with both PEG IFNs, showing SVR of 25% (at 1.5  $\mu\text{g}/\text{kg}/\text{wk}$ ) with PEG IFN- $\alpha$ -2b versus 12% for standard IFN at 3 mU three times weekly.<sup>263</sup> In another study, PEG IFN- $\alpha$ -2a at a dose of 180  $\mu\text{g}$  once weekly for 48 weeks was compared with IFN- $\alpha$ -2a at a dose of 6 mU three times weekly for 12 weeks and then 3 mU three times weekly for 36 weeks.<sup>261</sup> The SVR in the PEG IFN- $\alpha$ -2a group was 39% compared with 19% in the standard IFN group. Pegylated interferon plus ribavirin has thus become the new standard of care for the treatment of chronic hepatitis C.<sup>245</sup> In two large trials in which ribavirin was given in combination with PEG IFN or standard IFN, the overall rate of SVR was 54% for PEG IFN- $\alpha$ -2b versus 47% for standard IFN- $\alpha$ -2b,<sup>264</sup> and 56% for PEG IFN- $\alpha$ -2a versus 45% for standard IFN- $\alpha$ -2a.<sup>265</sup> Patients with genotypes 2 and 3 deserve special consideration. Sustained virologic responses with standard IFN and ribavirin were comparable to those with PEG IFN and ribavirin; therefore, standard IFN could be used in treating patients with these genotypes. Twenty-four weeks of therapy at an 800-mg daily dose of ribavirin seems sufficient for persons with

genotypes 2 and 3, while patients with genotype 1 need 48 weeks of treatment and 1000 to 1200 mg/day ribavirin.<sup>245,264,265</sup> In recent trials of PEG IFN and ribavirin, retrospective analysis yielded important information with significant impact on the management of patients with chronic HCV. Early virologic response (EVR) was defined as loss of HCV RNA or a decrease in HCV RNA by at least two log-fold compared with baseline values. By week 12 of therapy, 86% of patients treated with PEG IFN- $\alpha$ -2a plus ribavirin had achieved EVR. Of these, 65% subsequently achieved SVR. In contrast, among the 14% of patients without EVR by week 12, only 3% went on to SVR, resulting in a negative predictive value of 97%.<sup>266</sup> Similar findings are reported more recently in a study utilizing PEG IFN- $\alpha$ -2b and ribavirin.<sup>267</sup> Thus, in the absence of EVR, discontinuation of therapy should be considered.

Another important aspect to consider with therapy against HCV is histologic response. Poynard and colleagues compared 10 different regimes of PEG IFN- $\alpha$ -2b and conventional IFN with and without ribavirin and found that 24% of patients who received PEG IFN- $\alpha$ -2b (1.5 g/kg/wk) plus ribavirin achieved histologic response compared with only 16% on IFN monotherapy.<sup>268</sup> Camma and colleagues performed a meta-analysis of three studies on more than 1000 previously untreated patients with pretreatment and post-treatment liver biopsies to assess the differences between PEG IFN- $\alpha$ -2a and standard IFN- $\alpha$ -2a in terms of histologic improvement.<sup>269</sup> PEG IFN- $\alpha$ -2a induced a marked reduction in grade and stage in patients who achieved SVR, and no histologic benefit was seen for nonresponders after 24 to 48 weeks. Nonobese patients (body mass index <30 kg/m<sup>2</sup>) and those with high pretreatment ALT levels had the greatest probability of histologic response. Currently, the outcome for patients with advanced fibrosis is uncertain. The HALT-C (hepatitis C antiviral long-term treatment against cirrhosis) trial is a multicenter, randomized, controlled study sponsored by the NIH currently conducted at 11 centers in the United States, designed to determine whether long-term treatment with PEG IFN in previous nonresponders with advanced fibrosis can prevent or even reverse cirrhosis and reduce the risk of developing end-stage liver disease and HCC.<sup>270</sup> The results of this trial are eagerly awaited.

Patients with chronic hepatitis C and concurrent HIV infection may have an accelerated course of HCV disease.<sup>271</sup> Treatment with PEG IFN has not been evaluated in large-scale studies, but it should be offered to this special group of patients on a case-by-case basis.<sup>272</sup> Despite great advances in therapy of chronic hepatitis C in the last 15 years, 50% of patients still do not respond to therapy. Thus, there is a need for more effective therapies. Based on current knowledge of the HCV-encoded enzymes required for viral replication, many pharmaceutical manufacturers are pursuing the development of compounds that specifically inhibit enzymes critical to the HCV life cycle. Some potential targets are the HCV NS3/4A protease, the NS5B polymerase, and the viral IRES. Ribozymes designed to cleave the HCV IRES RNA have entered phase II clinical trials.<sup>273</sup> Histamine, acting via H<sub>2</sub> receptors on phagocytic cells, suppresses the activity of a key enzyme in oxygen radical formation, the NADPH oxidase.<sup>274</sup> By this mechanism, histamine protects NK cells and T cells against oxygen radical-induced dysfunction, reversing

immunosuppression caused by HCV-induced oxidative stress in the liver. Ongoing trials are evaluating the safety and efficacy of the triple combination of PEG IFN, ribavirin, and histamine in HCV-infected patients.<sup>274</sup> In the next few years new agents may be used alone or in combination with PEG IFN and ribavirin for the management of chronic hepatitis C.

## PREVENTION AND CONTROL

A major feature of HCV of great concern for vaccine development is the heterogeneity of its genome. The existence of quasispecies is one feature of HCV that helps it to evade host surveillance. There is also considerable heterogeneity in the nucleotide sequences, and likely antigenic characteristics of different strains and genotypes of HCV. While the cellular immune response seems to play an important role in the control of HCV infection, the existence and efficacy of neutralizing antibodies are less clear. A study performed in humans argues against a critical role of such antibodies in the resolution of infection.<sup>275</sup> However, no good test for neutralizing antibodies exists.

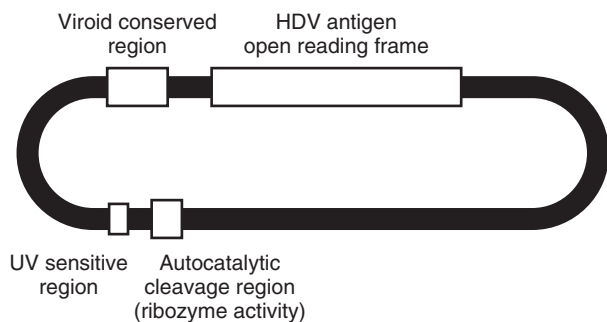

Currently no vaccine is available for the prevention of hepatitis C. Most of the focus to date is on the development of vaccines capable of inducing strong and long-lasting cell-mediated responses.<sup>276</sup> Progress in the understanding of the genomic organization of some viral agents has resulted in the production of recombinant vectors to deliver vaccine antigens and allow their endogenous expression by cells of the immunized host. Bruna-Romero and colleagues vaccinated mice with a recombinant adenovirus containing core and E1 genes of HCV.<sup>277</sup> Induction of a strong and long-lasting (up to 100 days) specific CTL response targeted against six different epitopes could be demonstrated. However, it is difficult to predict whether specific CTL responses in chronic HCV patients will exacerbate or control CTL-mediated liver injury.<sup>276</sup> Certainly, the vaccine developers face a great challenge. In the meantime, preventive measures directed at maximizing universal precautions, education of the population regarding high-risk behaviors, and careful screening of blood and organ donors are the only ways to prevent the transmission of this disease.

## ■ Hepatitis D

Hepatitis D virus (HDV) infection is caused by an RNA satellite virus, called delta ( $\delta$ ) hepatitis virus, that requires the presence of HBV for its complete life cycle. The HDV agent was discovered in 1977 by Rizzetto and associates<sup>278</sup> when a previously unrecognized antigen was seen by immunofluorescence in the nuclei of the hepatocytes of HBV-infected patients. In 1980 HDV transmission to HBV-infected chimpanzees established HDV as a distinct infectious agent.<sup>279</sup>

## AGENT

HDV is unique because it does not resemble any other animal virus and has not been formally classified.<sup>2</sup> A relationship of HDV to viroids, plant satellite viruses, and simple infectious RNA molecules has been proposed.<sup>280</sup> The HDV genome is the smallest among the human hepatitis viruses and is 1.68 kb in length. It is a single-stranded, circular RNA

**FIGURE 64-9** Hepatitis D anti-genome. UV, ultraviolet light. (From Koff RS, Dienstag JL, Riely CA, et al: AGA Clinical Teaching Project, Unit 3, Viral Hepatitis, 2nd ed. Timonium, Md., Milner-Fenwick, 1994.)

molecule (Fig. 64-9). The virion particles have an envelope composed of HBsAg that encloses the RNA genome along with the hepatitis delta antigen (HDAg). It is a negative-stranded RNA virus, since only the negative-strand RNA is packaged and found in the serum of infected patients. There is variability in the nucleotide sequence, and studies of the HDV genome in African patients suggest the existence of more than three genotypes of HDV.<sup>281</sup> Both the genome and the antigenome RNA contain autocatalytic cleavage sites with ribozyme activity, while the positive-sense antigenome contains an open reading frame for HDAg. HDV replication is regulated by two types of HDV antigens—the large form and the small form—which have identical sequences but differ in length by 19 amino acids owing to a C-terminal extension in the large delta antigen.<sup>282</sup> The longer protein inhibits HDV replication and participates in its packaging. The smaller HDAg protein promotes HDV RNA replication. Remarkably, these closely related proteins are the only proteins expressed by the virus. The key point for the clinician to understand, however, is that HDV replication is dependent on active expression of the HBV envelope protein, HBsAg, for packaging of the genome and completion of the HDV life cycle.

The RNA replication occurs in the hepatocyte nucleus, and extrahepatic sites have never been documented. The genomic RNA is copied by a rolling circle mechanism. An antigenomic strand is synthesized from the genome, and these antigenomic molecules self-cleave to form genome unit length fragments that self-ligate to a circular configuration. The new circle is used as a template to create new copies of the original molecule.<sup>51</sup> Interestingly, and in contrast with the other human hepatitis viruses, the viral RNA has enzymatic properties (ribozymes) that cleave and religate the viral RNA during the process of RNA replication; these ribozymes resemble those that occur in plant satellite viruses.<sup>51</sup>

## EPIDEMIOLOGY

HDV infection is found only in HBV-infected persons, but the prevalence of the two is not necessarily parallel. For instance, in southern Africa, where the prevalence of HBsAg carriers is around 15%, HDV is not found. Overall, HDV affects approximately 5% of HBV carriers worldwide.<sup>283</sup> In Italy, where HDV was originally described, its prevalence has decreased substantially in the past decade.<sup>2</sup> Other areas of

high prevalence are the Middle East, West Africa, and the Pacific Islands<sup>284</sup> as well as Eastern Europe.<sup>285</sup> In areas of low prevalence of HBV infection, infection with HDV affects mainly high-risk groups.<sup>278</sup> In the United States the prevalence of HDV among HBsAg-positive blood donors is low (1.4% to 8%) but is higher in HBsAg-positive IVDUs (20% to 53%) and hemophiliacs (48% to 80%).<sup>7</sup> The first report of HDV infection in South America occurred among Yupca Indians of Venezuela, who exhibited an HBsAg prevalence of 70%.<sup>286</sup> A form of fulminant hepatitis known for several decades in northern Colombia has been named “hepatitis of the Sierra Nevada de Santa Marta.” Up to 60% of HBsAg carriers in one village of this endemic area had antibody to hepatitis D antigen.<sup>287</sup> There is also a high incidence of HBV and HDV serologic markers among the residents of the Peruvian and Brazilian Amazon Basin.<sup>288–290</sup> Ten percent of Peruvian jungle residents (where the prevalence of HBsAg was 22.7%) had antibody to delta antigen,<sup>289</sup> and the foreign missionaries who worked in this area had a higher incidence of serologic markers for hepatitis B and D than did blood donors from the Peruvian coast.

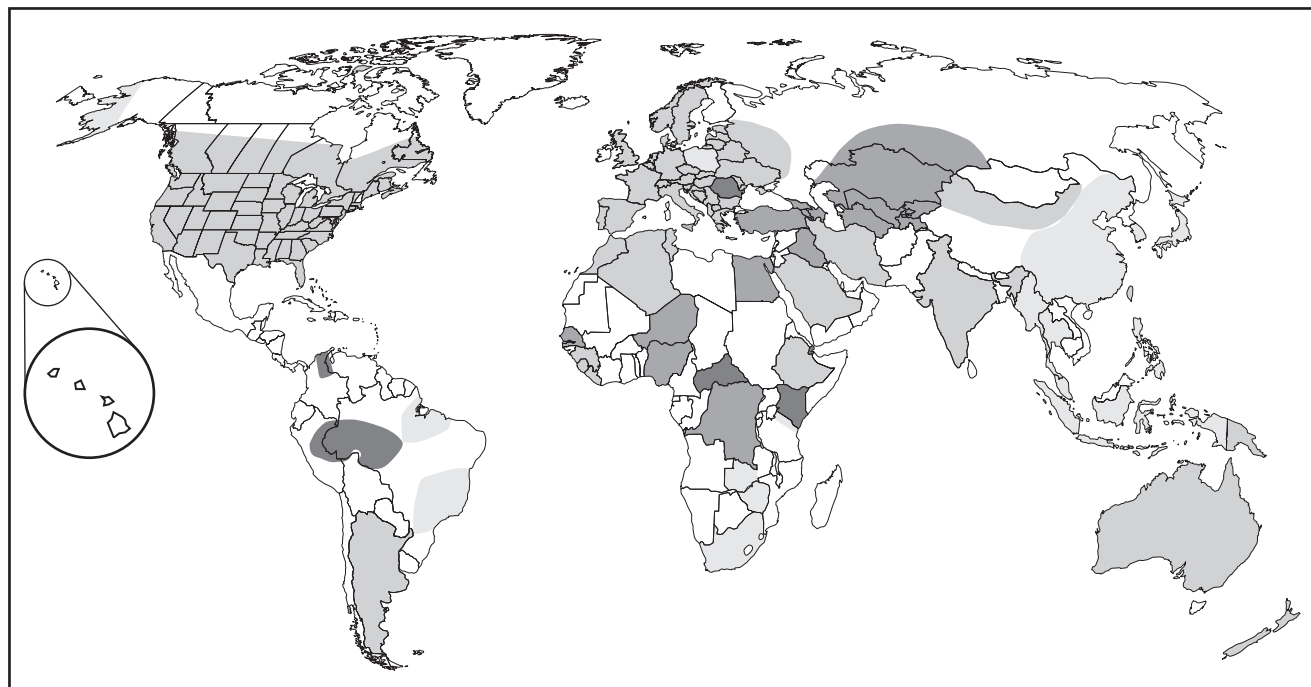

HDV infection is transmitted by the parenteral route through contact with blood or body secretions. Direct parenteral inoculation is the most efficient route, accounting for the epidemic dissemination of the HDV agent among IVDUs.<sup>291</sup> Post-transfusion HDV infection is a rare event, but the risk is higher in carriers of HBsAg<sup>292</sup> and in patients receiving multiple blood transfusions or blood products, as occurs in hemophiliacs. Sexual transmission of HDV is not so efficient as it is in HBV, and perinatal transmission has never been reported in the United States.<sup>10</sup> On the other hand, researchers have described seven groups of Brazilian Indians from the Amazon region, in whom sexual transmission was suggested as the most important mechanism of dissemination of HDV.<sup>293</sup>

## DISEASE

HDV infection can either occur simultaneously with HBV infection (coinfection) or as a superinfection in a person with chronic HBV infection. It is difficult, if not impossible, to differentiate hepatitis D from other types of viral hepatitis on clinical grounds alone. There is a wide spectrum of disease, from asymptomatic to end-stage liver disease. However, when compared with asymptomatic individuals having the HBsAg carrier state alone, subjects with HBsAg and anti-HDV antibodies have a fourfold risk of developing severe liver damage.<sup>294</sup> In some acute cases, a biphasic pattern of illness can be seen, in which the patient can have a second peak of ALT and a “flare” approximately 2 weeks after the presentation. This occurred in 23% of patients in a prospective study<sup>295</sup> and may be the only clinical clue to the presence of dual infection.

Patients with chronic hepatitis D may be asymptomatic or have nonspecific symptoms such as fatigue or vague right upper quadrant discomfort. Approximately 25% may have well-established cirrhosis at presentation.<sup>296</sup> Coinfection with HDV and HBV follows the natural history of acute uncomplicated hepatitis B, with a rate of chronicity of less than 5%. This is probably due to the inability of HDV to continue to replicate without HBV. In a prospective study of IVDUs with HBV-HDV coinfection, only 2.4% developed chronicity.<sup>297</sup>

### Hepatitis D

#### HDV Prevalence

■ High

■ Intermediate

■ Low

■ Very Low

□ No Data

On the other hand, with superinfection, chronicity is the rule, and up to 70% of patients develop cirrhosis at some point. There is, however, a possible variability in the biologic behavior of HDV between different geographic areas. For instance, in a Chinese study involving follow-up for 8 years in patients with superinfection, the rate of progression to cirrhosis was not statistically different from that of HBsAg carriers.<sup>298</sup>

Besides accelerating the course of HBV-related chronic liver disease, HDV is highly associated with fulminant hepatitis,<sup>299</sup> which is more commonly seen with superinfection than with coinfection.<sup>295</sup> Additionally, mortality of patients with fulminant hepatitis is higher in patients with superinfection.

The association between HDV infection and HCC is controversial. Verme and coworkers<sup>300</sup> showed that patients with HDV and HCC were younger than HBV carriers with negative markers for HDV, suggesting that the dual infection triggers a more severe necroinflammatory reaction that leads to neoplastic transformation.

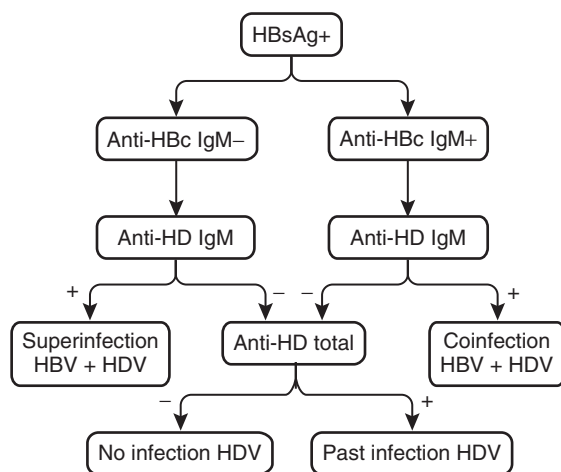

### PATHOGENESIS AND IMMUNITY

HDV is absolutely dependent on HBV for its replication and pathogenicity, since the HDV RNA is packaged by the HBV envelope protein, HBsAg. Because of its dependence on HBV, HDV can only infect a person who is already a carrier of HBV (superinfection) or who is simultaneously being infected with HBV (coinfection). In superinfection, HDV replication

suppresses HBV replication, seemingly at the transcriptional level.<sup>301</sup> Therefore, superinfection with HDV may be associated with a reduction in intrahepatic levels of HBsAg, HBeAg, and HBV DNA.<sup>302</sup> According to some studies, the pathogenesis of HDV can be explained by two mechanisms: by direct cytopathic action of HDV expressing HDV antigen in the hepatocyte membrane or by replication of HDV RNA and subsequent cellular destruction.<sup>303</sup> Autoimmunity has been described in HDV infection, with the documentation of antiliver, -kidney, and -microsomal (LKM) antibodies.<sup>278</sup>

HDV RNA and HDV antigen (HDAg) are detected early, concurrent with the detection of HBsAg. As HBsAg disappears, HDAg is also cleared and anti-HDV antibodies appear, initially IgM and later IgG. These antibodies are usually detectable late and not at the onset of symptoms. Sometimes the early appearance of isolated IgM anti-HDV or the presence of convalescent titers of IgG anti-HDV may be the only serologic evidence of HDV infection.

In the case of superinfection, HDAg and HDV RNA usually remain detectable in serum, along with high titers of IgM and IgG anti-HDV.<sup>304</sup> The course of HDV infection might be modified by multiple factors, such as acute HDV infection in carriers of mutant variants of HBV.<sup>305</sup> In this scenario, replication of HDV occurs with less efficiency owing to less functional HBV, leading to a more benign course. Not much is known about the cellular response of the immune system in the setting of HDV infection.

**FIGURE 64-10** Algorithm for the evaluation of a patient infected with hepatitis D. HBsAg, hepatitis B surface antigen; HBe, hepatitis B core antigen; HBV, hepatitis B virus; HD, hepatitis D; HDV, hepatitis D virus.

## DIAGNOSIS

The serodiagnosis of HDV coinfection and superinfection is slightly different (see Pathogenesis and Immunity). An algorithm shows the interpretation of the different clinical scenarios of HBV/HDV interactions (Fig. 64-10). The hallmark of the diagnosis in both situations is the presence of anti-HDV, which can be measured by radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA). The serologic response to HDV is not so strong or consistent as occurs with hepatitis A or B. The IgM and IgG responses are usually strong in superinfected HBsAg carriers developing chronic HDV infection.<sup>306</sup> In the case of coinfection, some patients may express only IgM or IgG or may have both the primary IgM and secondary IgG responses. The most important diagnostic marker for hepatitis D is IgM anti-HDV, and its presence correlates with ongoing liver inflammation and predicts progression to cirrhosis.<sup>307</sup> Therefore, unlike in hepatitis A and B, in HDV infection the presence of IgM antibody is not necessarily diagnostic of acute infection.

HDAg can be detected in serum, although only in the early stages of infection before the appearance of anti-HDV, because the antigen forms complexes with antibody becoming masked, owing to the usually high titers of antibody.<sup>308</sup> The more sensitive Western blot analysis allows detection of lower levels of HD antigenemia. This technique involves ultracentrifugation and detergent treatment of viral particles, followed by electrophoresis and detection of the antigen by a radiolabeled antibody. Viremia can also be demonstrated by direct detection of HDV RNA using RT-PCR<sup>309</sup> or molecular hybridization assays.<sup>310</sup>

Performance of a liver biopsy is indicated to assess disease stage and prognosis, but no histologic features are pathognomonic for HDV.<sup>311</sup> The presence of intrahepatic HDAg can be visualized by immunofluorescence of the tissue sample, appearing as nuclear staining in hepatocytes,<sup>312</sup> and this is considered the "gold standard" by many authorities.

## TREATMENT AND PROGNOSIS

There is no effective therapy for acute hepatitis D, and treatment is essentially directed to patients with chronic

HDV infection. Rosina and colleagues conducted a 12-month randomized controlled trial with IFN in 61 Italian patients with chronic delta hepatitis.<sup>313</sup> The patients were randomly assigned to receive either IFN 5 mU/m<sup>2</sup> three times daily for the first 4 months and then 3 mU/m<sup>2</sup> three times daily for the remaining 8 months or no treatment. Despite a greater reduction of ALT levels in the treated group, the serum HDV RNA, intrahepatic HDAg, and histologic activity index scores were not statistically different between treatment and control groups at any given time. Another study compared IFN in doses of 9 mU or 3 mU three times daily versus no treatment for 48 weeks.<sup>314</sup> Fifty percent of the patients treated with the higher dose regimen had a complete response (defined as complete normalization of ALT and undetectable HDV RNA) compared with only 21% of those who received the lower dose regimen and none of the controls. In addition, there was significant histologic improvement in the group that received the higher dose compared with the other two groups. Remarkably, despite the high dosage and prolonged treatment period, all patients completed the 48-week course of therapy.

Agents developed to treat chronic hepatitis B, such as the nucleoside analog lamivudine or adefovir dipivoxil, may prove to be useful in managing chronic delta hepatitis by inhibiting HBV replication, but there are currently no published trials assessing the efficacy of these drugs in the setting of HDV infection. These agents rarely result in termination of HBsAg expression, which is the HBV protein that provides the necessary helper function to HDV. Potential targets for HDV therapy in the future may include inhibitors of HDAg phosphorylation, HBsAg glycosylation, or inhibitors of HDV RNA ribozyme activity.<sup>315</sup> The serious nature of chronic delta hepatitis is a challenge requiring development of novel therapeutic approaches.

## PREVENTION AND CONTROL

Since the HDV RNA is packaged by the HBV envelope protein, HBsAg, antibodies to HBsAg are protective against HDV infection. Thus, immunization against HBV also provides protection against HDV in HBV-naïve individuals. However, for HBV carriers, no effective vaccine is available to specifically protect against HDV. A study utilizing preparations of HDAg to vaccinate woodchucks with chronic woodchuck hepatitis virus infection against HDV infection failed to show a protective effect of the vaccine.<sup>316</sup> Patients already infected with HBV should be strongly advised against using contaminated needles or engaging in high-risk sexual practices to avoid superinfection with HDV. The annual incidence of HDV infection seems to be steadily falling worldwide.

## Hepatitis E

Hepatitis E is an enterically transmitted form of viral hepatitis that appears to be common in tropical and subtropical areas, and epidemics have been reported in Asia, Africa, the Middle East, and Central America.<sup>1</sup> It is a distinct agent that has been associated with fulminant hepatic failure among pregnant women but has no known chronic sequelae.

An extensive outbreak of waterborne hepatitis was reported in India in 1955. In further retrospective analysis 25 years later, all stored serum samples were found to have

IgG anti-HAV, but not IgM anti-HAV, evidence against the assumption that the etiologic agent responsible for this outbreak was HAV.<sup>317</sup> This was the first of many documented outbreaks of “waterborne non-A, non-B hepatitis.” Subsequently, similar outbreaks were reported and especially associated with a high fatality rate among pregnant women in Southeast Asia.<sup>318</sup> In 1990 the genome of the virus was cloned and designated hepatitis E virus (HEV),<sup>319</sup> allowing the development of specific diagnostic tests and expanding the knowledge about this agent.

## AGENT

HEV has not been classified. Immunoelectron microscopy permitted the detection of spherical, nonenveloped HEV particles measuring approximately 32 nm, similar to those of the family *Caliciviridae*.<sup>320</sup> The virus exhibits spikes and indentations in the particle surface that give it a feathery aspect. However, its positive-strand RNA genome shows closer genetic relatedness to the alphaviruses. The virus particle appears to be degraded by exposure to cesium chloride and storage at  $-20^{\circ}\text{C}$ .

The RNA genome of HEV (Fig. 64-11) is 7.5 kb in length, shows positive polarity, and has three separate, partially overlapping open reading frames that encode structural and nonstructural proteins. The putative nonstructural genes are located at the 5′ end, and the structural genes are located at the 3′ end of the genome.<sup>321</sup> The first open reading frame (ORF1) is approximately 5 kb in length and encodes nonstructural proteins: the RNA-dependent RNA polymerase, RNA helicase, methyltransferase, and a cysteine protease. ORF2 encodes the major structural proteins of HEV. The smallest ORF (ORF3) encodes a protein with intercalated hydrophobic and hydrophilic regions of unknown function. Eight different genotypes have been identified to date: Burma (type 1), Mexican (type 2), North American (type 3), Chinese (type 4), European (types 5, 6, and 7), and the most recently discovered Argentinian (type 8).<sup>322</sup> The existence of more genotypes is a possibility, as suggested by Austrian investigators who recently isolated the variant HEV-Au1.<sup>323</sup> Despite differences in genotypes, only one serotype explains cross-reactivity for the main viral epitopes, allowing serologic diagnosis with commercially available kits.<sup>324</sup>

## EPIDEMIOLOGY

Epidemics of HEV infection have been described throughout Asia, large parts of northeastern and eastern Africa, and Mexico.<sup>325–330</sup> Hepatitis E is implicated in about 50% of

sporadic cases of acute viral hepatitis in developing countries.<sup>327</sup> North America and Europe have traditionally been considered nonendemic for HEV, although seroprevalence ranges from 1% to 5%.<sup>331</sup> In the last few years some HEV strains associated with sporadic acute hepatitis have been isolated from human serum samples in North America.<sup>332</sup> Clemente-Casares and colleagues analyzed the excreted virus in the urban sewage of Barcelona (Spain) and other countries including the United States (Washington, DC, area), Greece, France, and Sweden.<sup>333</sup> Eighty-four percent of sewage samples from Barcelona tested positive for HEV RNA. One of five samples from Washington, DC, and one of four samples from France were positive. HEV RNA was not detected in any of the samples from Greece or Sweden. These data suggest that HEV strains are more widespread than previously thought, and rare HEV infections may occur in Europe and the United States. HEV is endemic in some regions of South America.<sup>334</sup> HEV attacks mostly young adults and is rarely seen in children younger than 15 years of age,<sup>327</sup> in contrast to HAV infection, which is a rare event in adults in developing countries owing to long-standing immunity against the virus acquired in childhood. Antibody tests are neither widely available for this virus nor well standardized. However, some data concerning seroprevalence have been reported. In Egypt, the seroprevalence of anti-HEV exceeds 60% in the first decade of life, peaks at 76% in the second decade, and remains above 60% until the eighth decade.<sup>335</sup> This is the highest prevalence in the world reported for HEV. Seroconversion to anti-HEV was documented in 4 of 211 travelers from the United States to Thailand, Russia, China, and Peru.<sup>336</sup> None of the individuals reported any symptoms of hepatitis before, during, or after travel, implying that exposure to HEV resulted in subclinical infection.

Animal reservoirs of HEV exist in many regions, and human infections may result from a zoonotic focus. HEV has been identified in 22% of pooled stool samples from 115 swine farms in the Netherlands.<sup>337</sup> Ninety percent of wild rats from Hawaii, 77% from Maryland, and 44% from Louisiana were seropositive for HEV.<sup>338</sup> In Vietnam, where hepatitis E is endemic, anti-HEV has been detected in 44% of chickens, 36% of pigs, 27% of dogs, and 9% of rats.<sup>339</sup> Swine veterinarians in eight different states of the United States were 1.5 times more likely to be anti-HEV positive than were other blood donors.<sup>340</sup> A closely related virus is highly prevalent among commercially raised swine in the United States.

Person-to-person transmission is a potential route of infection, as suggested by the epidemiologic pattern of the Mexican outbreak.<sup>330</sup> Pregnant women in the third trimester are at high risk of developing fulminant hepatitis,<sup>326</sup> probably the most prominent epidemiologic feature of this disease. Possible parenteral transmission of HEV can occur, as suggested by a hospital outbreak of hepatitis E.<sup>341</sup>

## DISEASE

The incubation period of hepatitis E is approximately 40 days (2 to 8 weeks).<sup>324</sup> It is typically a self-limited disease and cannot be distinguished from other forms of viral hepatitis based solely on clinical features. However, it should be suspected in any person with acute hepatitis, a history of recent travel to underdeveloped areas, and negative serologic tests for hepatitis A, B, and C.

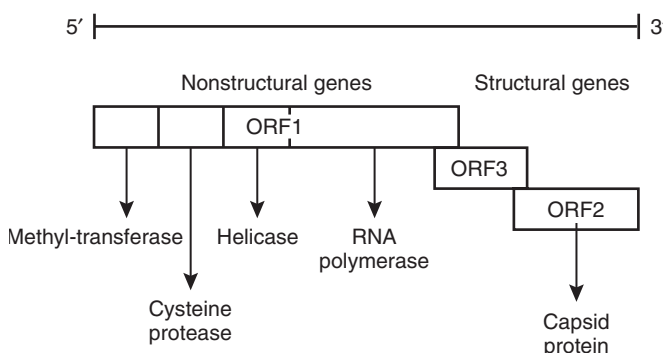

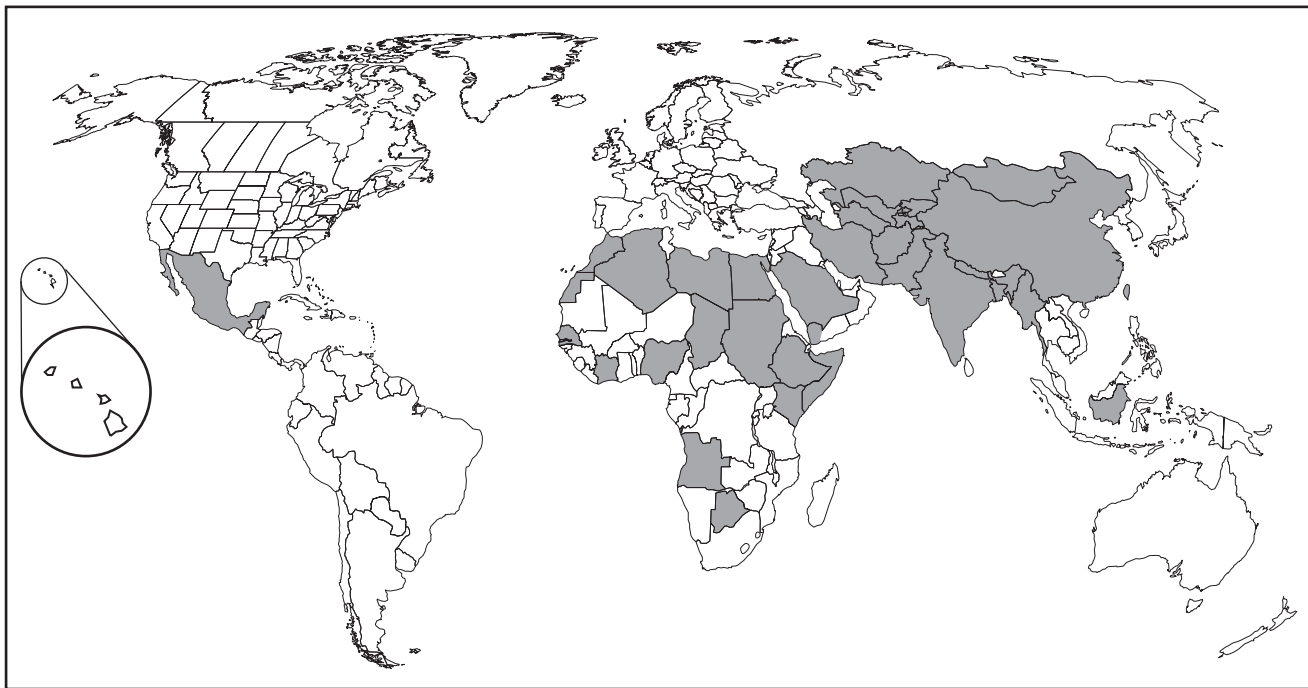

FIGURE 64-11 Hepatitis E genome.

Hepatitis E

Fever, arthralgias, general malaise, and nausea are common manifestations. In a case of self-inoculated HEV infection in a human volunteer,<sup>342</sup> the symptoms started 4 weeks after inoculation, and the icteric phase lasted for about 4 months. Two years after complete recovery, this volunteer still had IgG anti-HEV detectable in serum. There have been no case reports of chronic hepatitis E infection to date.

Severe disease typically occurs in pregnant women during the third trimester, with a mortality rate of about 20%.<sup>2,336,343</sup> All nine pregnant women in an outbreak in Algeria died of fulminant hepatic failure.<sup>343</sup> This predilection for fulminant hepatitis in pregnant women is not seen in other forms of viral hepatitis, and there is no clear pathophysiologic explanation for its catastrophic occurrence. Sera from 22 patients with fulminant hepatitis in Bangladesh showed anti-HEV IgM in 63.6%, being the most common cause of fulminant viral hepatitis in that series.<sup>344</sup>

### **PATHOGENESIS AND IMMUNITY**

HEV replicates in the liver and is excreted in the feces via the biliary tract. This process has been extensively studied in non-human primates after inoculation with fecal samples obtained from patients with HEV infection.<sup>345</sup> Pathologic changes in the liver during acute HEV infection can vary from canalicular cholestasis to ballooning degeneration of the hepatocytes and acute portal inflammatory infiltrates.

HEV particles appear in feces during prodromal symptoms of hepatitis E, which can be associated with a viremic phase. Several weeks after exposure, HEV antigen appears in blood, and antibody responses develop approximately 1 month later, coincident with the ALT peak. The first antibody detected is IgM, which declines during the convalescent phase. Simultaneously IgG anti-HEV appears. The duration of detectable antibody is unknown.<sup>346</sup>

Twelve immunoreactive epitopes have been identified in ORF1 within the region of the RNA-dependent RNA polymerase,<sup>347</sup> three epitopes in ORF2, and one in ORF3. However, not much is known about the pattern of responses that determine clinical outcome. It is postulated that antibody tests could be developed to differentiate between true viral infection and prior immunization with a structural protein, since antibodies against nonstructural proteins should not be found in subjects who were immunized with only structural proteins.<sup>347</sup>

### **DIAGNOSIS**

A sensitive and specific Western blot assay capable of detecting anti-HEV in both acute and convalescent phase sera has been developed.<sup>347,348</sup> Immunofluorescent techniques detect the presence of IgM (acute phase) and IgG (convalescent phase),<sup>349</sup> and various ELISA methods have been shown to be sensitive and specific.<sup>347</sup> An assay for IgA anti-HEV has been described,<sup>350</sup> being detected in 52.4% of patients; 73.1% were also positive for IgM anti-HEV, both isotypes of antibodies disappearing during the convalescent phase of the infection. The RT-PCR technique has been used to detect HEV in stools of acutely infected patients, but it is still considered a research tool.<sup>351</sup> In 1995 infections among a group of United Nations Bangladeshi peace keepers in Haiti was diagnosed by direct HEV RNA determination, permitting infection control and preventing dissemination of the disease.<sup>352</sup>

### **TREATMENT**

There is currently no effective treatment for HEV infection other than general supportive measures (see Treatment for hepatitis A).

## PREVENTION AND CONTROL

Boiling water before use during epidemics of HEV reduces disease transmission.<sup>328</sup> Travelers to endemic areas and especially pregnant women in their last trimester should avoid ingesting uncooked food and potentially contaminated water. Immunoglobulin preparations are not protective, even when obtained from donors living in endemic areas.<sup>327</sup>

Purdy and colleagues immunized two cynomolgus macaques with trpE-C2 protein, which represents the carboxyl two thirds of the HEV capsid protein.<sup>353</sup> After challenge with wild-type HEV from stool isolates, neither vaccinated animal developed elevation in ALT level, in contrast to the control macaques. A recombinant protein vaccine for hepatitis E appears promising on the basis of animal studies. A clinical study examining the protective efficacy of this vaccine is ongoing in Nepal.

## Overview of Viral Hemorrhagic Fevers

C. J. PETERS  
SHERIF R. ZAKI

### INTRODUCTION

Several viruses regularly cause a syndrome that is referred to as hemorrhagic fever (HF). They belong to four different families of RNA viruses, but all are lipid enveloped and zoonotic in their maintenance strategies. The taxonomy is helpful in understanding their natural history and pathogenesis but does not accurately predict the clinical syndromes following infection with a given family member. For example, virtually all the arenaviruses are maintained by chronic infection of a single rodent host and spread to humans by aerosols of rodent excreta and related mechanisms, with the details of the human epidemiology mainly predictable by rodent dynamics and human behavior. However, Tamiami and Whitewater Arroyo viruses are North American arenaviruses not associated with any disease, and the best known American arenavirus is lymphocytic choriomeningitis virus, which came to the Americas when the common house mouse, *Mus musculus*, was introduced in post-Columbian times. Lymphocytic choriomeningitis virus infection of humans mainly causes subclinical infection, acute undifferentiated febrile disease, and febrile central nervous system illnesses such as aseptic meningitis, but two cases have resembled the HF syndrome.

### AGENT

The HF viruses occur worldwide (Table 65-1) and the geographic site of infection is an important determinant of the risk to an individual patient. The geography and knowledge of the incubation period are important in suspecting an exported viral HF. The syndrome characteristically begins with fever, myalgia, and malaise, which then progress to prostration, gastrointestinal and other system involvement, and signs of vascular damage. Involvement of the vascular system is usually manifest by vascular dysregulation (mild hypotension, postural hypotension, flushing, and injected conjunctivae), vascular damage (nondependent edema and organ dysfunction), and hemorrhage. Hemorrhage is usually diffuse in microvascular beds throughout the body and occurs particularly in patients with thrombocytopenia or marked platelet dysfunction. Many patients have little or no bleeding, but some present with extensive cutaneous and mucosal hemorrhage. Severe cases will have shock, central nervous system

involvement, or extensive hemorrhagic phenomena. The clinical findings in the different HFs vary in a characteristic way for each virus, but any individual patient is difficult to classify without virologic diagnosis (Tables 65-2 and 65-3). The detailed manifestations of each VHF are often based on fragmentary clinical observations and lack proper appreciation of the entire spectrum, which in some cases includes such manifestations as pancreatitis.

### PATHOGENESIS

Although there are common themes, the different viruses also differ in their pathology and pathogenesis (Table 65-4). Usually, hemorrhages are present in many organs, and effusions are commonly found in serous cavities, but they may be minimal or absent in some patients. There is widespread necrosis, which may be present in any organ system and that varies from modest and focal to massive in extent. Liver and lymphoid systems are usually extensively involved, and the lung regularly has varying degrees of interstitial pneumonitis, diffuse alveolar damage, and hemorrhage. Acute tubular necrosis and microvascular thrombosis may also be seen. The inflammatory response is usually minimal. These changes, which may be a direct effect of viral infection or a consequence of cytokine secretion, have considerable variation among the different viruses (see Table 65-4).

### DIAGNOSIS

Correct diagnosis in most of the diseases depends on demonstration of the infecting virus or one of its products in acute serum samples. Viral antigens are readily demonstrable, and often an antigen detection enzyme-linked immunosorbent assay (ELISA) is the best test for identifying patients because of its rapidity and robustness; it is particularly likely to be positive in the more severely ill patient, who is in greatest need of therapy and who may provide the greatest risk of dissemination. Reverse transcription-polymerase chain reaction (RT-PCR) is usually more sensitive but also more subject to artifact and contamination. RT-PCR has a unique role in providing an amplicon that can be sequenced for genetic analysis, although this very genetic variation may be a source of difficulty in ensuring that appropriate primers are applied to unknown samples. In general, viremia and antigenemia are readily detected during the acute phase and disappear as the patient improves. RT-PCR is usually positive during the same period and perhaps 1 or 2 days longer. IgM antibodies may be detectable during illness and usually appear early in convalescence, providing a sensitive, specific method of diagnosis, particularly if they are measured by an IgM capture ELISA technique. Diagnosis of initial patients in any outbreak, particularly if there are unusual features, benefits from study of virus isolates and classic serologic responses, particularly the neutralization test, animal pathogenesis, and genomic analysis. Most of the viruses are hazardous and should only be isolated or studied under BSL4 containment. Hantaviruses are an exception to the generalizations: The patients typically present with an ongoing immune response and are best diagnosed with the IgM capture ELISA; virus isolation is difficult, but RT-PCR on acute blood clot may give valuable genetic information about the infecting virus.

Table 65-1 Geography and Epidemiology of Hemorrhagic Fever Viruses

Virus	Disease	Geography	Vector/Reservoir	Human Infection
Arenaviridae Junin Machupo Guanarito Sabia Lassa	Argentine HF	Argentine pampas	Chronic infection of small field rodent, <i>Calomys musculus</i> .	<p>Infects agricultural workers disproportionately. Major transmission in fall: Aerosol transmission to humans. Rural residents and farmers main target; rodent can invade towns to cause epidemics. Aerosol transmission to humans. Interhuman transmission not usual, but occurs. Rural residents in recently developed area with small farms.</p> <p>Single infection observed in nature: little information on epidemiologic potential.</p> <p>The reservoir rodent is very common in Africa, and the disease is a major cause of severe febrile illness in West Africa. Spread to man occurs by aerosols and by capturing the rodent for consumption, as well as person-to-person transmission. Lassa fever is the most commonly exported HF.</p>
	Bolivian HF	Beni Department, Bolivia	Chronic infection of small field rodent, <i>Calomys callosus</i> .	
	Venezuelan HF	Portuguesa state, Venezuela	Chronic infection of field rodent, <i>Zygodontomys brevicauda</i> .	
	Brazilian HF	Rural area near São Paulo, Brazil	Presumably chronic infection of unidentified rodents.	
	Lassa fever	West Africa	Chronic infection of rodents of the genus <i>Mastomys</i> .	
Bunyaviridae Rift Valley fever	Rift Valley fever	Sub-Saharan Africa	Vertical infection of floodwater <i>Aedes</i> mosquitoes. Epidemics occur from horizontal transmission by many different mosquito species between domestic animals, particularly sheep and cattle.	<p>Humans acquire virus by mosquito bite; contact with blood of infected sheep, cattle, or goats; and aerosols generated from infected domestic animal blood. No interhuman transmission observed.</p>
	Crimean-Congo HF	Africa, Middle East, Balkans, southern Russia, western China	Tick-mammal-tick infection. Vertical infection occurs in ticks. <i>Hyalomma</i> ticks are thought to be the natural reservoir, but other genera may become infected and transmit.	
Hantaan, Seoul, Puumala, and others	Crimean-Congo HF	Worldwide depending on rodent reservoirs	Horizontal infection in a single rodent genus or species typical of the virus. Viruses associated with HFRS have been obtained from Muridae (subfamilies Murinae or Avicolinae) rodents (rats, mice, and voles).	<p>Tick bite; squashing ticks; and exposure to aerosols or fomites from slaughtered cattle and sheep. (Domestic animals do not show illness but may become infected when transported to market or when held in pens for slaughter.) Nosocomial epidemics observed on numerous occasions.</p> <p>Aerosols from freshly shed urine of infected rodents. Some infections may be acquired from secondary aerosols or droplets from previously shed rodent excreta and secreta or from rodent bites. Interhuman transmission never documented.</p>

Continued

Table 65-1 Geography and Epidemiology of Hemorrhagic Fever Viruses—cont'd

Virus	Disease	Geography	Vector/Reservoir	Human Infection
Sin Nombre, Black Creek Canal, Bayou, and others	Hantavirus pulmonary syndrome (HPS)	Americas	As for hantaviruses causing HFRS. All viruses associated with HPS have come from Muridae (subfamily Sigmodontinae) rodents, if the reservoir is known.	As for hantaviruses causing HFRS. Entering abandoned, closed buildings may be a particular risk in some settings. Interhuman transmission rarely observed with Andes virus
Flaviviridae				
Marburg, Ebola	Marburg HF Ebola HF	Africa, ?Philippines	Unknown	Infection of index case occurs from unknown source. Infected nonhuman primates sometimes provide link to humans. Later spread among human or nonhuman primates by close contact with another case. Aerosol transmission suspected in one captive monkey outbreak.
Flaviviridae				
Yellow fever	Yellow fever	Africa, South America	Mosquito–monkey–mosquito maintenance with occasional human infection when unvaccinated humans enter forest. Large epidemics among humans with <i>Aedes aegypti</i> as mosquito vector.	Mosquito infection of humans entering forest and encountering infected sylvatic vector. Emergence of epidemics into African savannas via specific <i>Aedes</i> mosquito vectors. In cities or villages, interhuman transmission by <i>Ae. aegypti</i> . Fully developed cases are no longer viremic and direct interhuman transmission not believed to be a problem although the virus is highly infectious (including aerosols) in the laboratory. DHF/DSS is a problem in areas where multiple dengue viruses are being transmitted. With the increased worldwide distribution of <i>Ae. aegypti</i> and movement of dengue viruses in travelers, this zone is enlarging. The disease was first noted in Southeast Asia but is now common in the Americas and the Caribbean, as well as the Pacific rim countries.
Dengue (types 1–4)	Dengue HF (DHF), dengue shock syndrome (DSS)	Tropics and subtropics worldwide	Maintained by <i>Ae. aegypti</i> –human– <i>Ae. aegypti</i> transmission with frequent geographic transport of viruses by travelers.	Most infections occur from tickbite acquired in rural areas of the endemic zone. Monkey die offs may accompany increased virus activity. Few cases in recent years.
Kyasanur Forest disease (KFD) Omsk HF (OHF)	KFD OHF	Karnataka state, India Western Siberia	Tick–vertebrate–tick Poorly understood cycle involving ticks, voles, muskrats, and possibly water-borne and mosquito transmission.	
Al Kumrah		Middle East? Africa?	Unknown. Surmised to involve tick–domestic livestock–tick cycle by analogy to genetically related tick-borne flaviviruses.	Transmitted to humans working in livestock-related occupations by unknown route. Genetically related to KFD virus.

HF, Hemorrhagic fever.

**Table 65-2** Clinical Features of the Viral Hemorrhagic Fevers

Disease	Incubation Period (Days)	Case Infection Ratio	Case Fatality	Characteristic Features
Arenaviridae South American HF	7–14	Most (>1/2) result in disease	15%–30%	Typical cases have hypotension, shock, obvious bleeding, and neurologic symptoms such as dysarthria and intention tremor. Some cases have virtually pure neurologic syndrome.
Lassa fever	5–16	Mild infections probably common	2%–15%	Prostration and shock; fewer hemorrhagic or neurologic manifestations than South American HF except in severe cases. Thrombocytopenia less common and less severe. Deafness develops in convalescence in 20%.
Bunyaviridae Rift Valley fever	2–5*	≈1%	≈50%	Severe disease associated with bleeding, shock, anuria, and icterus. Encephalitis and retinal vasculitis also occur, but without overlap with HF syndrome.
Crimean-Congo HF HF with renal syndrome	3–12 9–35	20%–100% >3/4 Hantaan virus	15%–30% 5%–15%	Most severe bleeding and ecchymoses of all the HFs.
Hantavirus pulmonary syndrome	7–28	1/20 Puumala virus Very high	Hantaan virus <1% Puumala virus 40%–50%	Febrile stage followed by shock and renal failure. Bleeding during febrile stage, shock, and renal failure. Puumala virus infections have a similar course but are much milder.
<i>Filoviridae</i> Marburg or Ebola HF	3–16	High (particularly Zaire subtype of Ebola)	25%–90%	Febrile stage followed by acute pulmonary edema and shock. Manifestations largely limited to thoracic cavity.
Flaviviridae Yellow fever	3–6	50% of nonimmune <5% of heterologous flavivirus immune	20%–50%	Most severe of the HFs. Marked weight loss and prostration. Maculopapular rash common. Patients have had late sequelae (hepatitis, uveitis, orchitis) often with virus isolation from biopsy or aspiration.
Dengue HF (DHF), dengue shock syndrome (DSS)	3–15*	0.007% of nonimmune and 1.0% of heterologous immune	Untreated, 10%–15% Treated, <1%	Acute febrile period with defervescence accompanied in severe cases by jaundice and renal failure.
Kyasanur Forest disease (KFD) Omsk HF	3–8	Variable	0.5%–9.0%	High fever for 3–5 days with the development of shock lasting 1–2 days. DHF is not equated to DSS. DSS is the most dangerous manifestation and is due to an acute vascular leak. Attack rates, mortality quite variable with epidemic virus strain and surveillance.
				Typical biphasic disease with a febrile or hemorrhagic period often followed by CNS involvement. Similar to tick-borne encephalitis except hemorrhagic manifestations are not characteristic of first phase of tick-borne encephalitis.

HF, Hemorrhagic fever.

\*Uncomplicated disease; incubation for HF may differ.

**Table 65-4** *Viral Tropism and Pathologic Features of Viral Hemorrhagic Fevers*

Disease	Pathologic Features*
<b>Arenaviridae</b>	
Argentine HF	Multifocal hepatocellular necrosis with minimal inflammatory response, interstitial pneumonitis, myocarditis, and lymphoid depletion; extensive parenchymal cell and reticuloendothelial infection, more than morphologic lesions would suggest.
Bolivian HF	
Venezuelan HF	
Lassa fever	
<b>Bunyaviridae</b>	
Rift Valley fever (RVF)	Widespread hepatocellular necrosis and hemorrhage, sometimes with midzonal distribution, minimal inflammatory response, disseminated intravascular coagulation, lymphoid depletion; RVF antigens in few individual hepatocytes; encephalitis and retinal vasculitis also seen.
Crimean-Congo HF	Widespread hepatocellular necrosis and hemorrhage with minimal or no inflammatory cell response and lymphoid depletion; hepatic and endothelial cell infection and damage.
Hemorrhagic fever with renal syndrome (HFRS)	Retroperitoneal edema in severe HFRS, mild to severe renal pathologic changes; congestion and hemorrhagic necrosis of renal medulla, right atrium of the heart, and anterior pituitary; extensive endothelial infection mainly in renal and cardiac microvasculature.
Hantavirus pulmonary syndrome (HPS)	Large bilateral pleural effusions and severely edematous lungs, mild to moderate interstitial pneumonitis, immunoblasts, and atypical lymphocytes in lymphoid tissues and peripheral blood; extensive infection of endothelial cells in pulmonary microvasculature.
<b>Filoviridae</b>	
Ebola HF	Extensive and disseminated infection and necrosis in major organs such as liver, spleen, lung, kidney, skin, and gonads; extensive hepatocellular necrosis associated with formation of characteristic intracytoplasmic viral inclusions; lymphoid depletion, microvascular infection, and injury.
Marburg HF	Similar to Ebola HF.
<b>Flaviviridae</b>	
Yellow fever	Midzonal hepatocellular necrosis; minimal inflammatory response; Councilman bodies and microvesicular fatty change; hepatocellular and Kupffer cell infection; lymphoid necrosis (nodes, spleen); focal myocarditis; acute renal tubular necrosis.
Dengue HF, dengue shock syndrome	Centrilobular and midzonal hepatocellular necrosis with minimal inflammatory response; Councilman bodies and microvesicular fatty change; hyperplasia of mononuclear phagocytic cells in lymphoid tissues and atypical lymphocytes in peripheral blood; widespread infection of mononuclear phagocytic and endothelial cells.
Kyasanur Forest disease (KFD)	Focal hepatocellular degeneration, fatty change, and necrosis; pulmonary hemorrhage, depletion of malpighian follicles, sinus histiocytosis, erythrophagocytosis, mild myocarditis, and encephalitis.
Omsk HF	Little known; scattered focal hemorrhage, interstitial pneumonia, and normal lymphoid tissues.

HF, Hemorrhagic fever.

\*These features represent the characteristic pathologic findings in the different viral HFs. More general findings seen to variable degrees in all HFs are not listed.

Ideally, blood samples from HF patients should be collected early in the course of illness, and both serum and blood clot should be frozen as soon as possible. A second sample should be obtained before discharge or death for comparative serology, and this can be supplemented by a later follow-up blood sample. In fatal cases, a full autopsy should be performed with a complete set of organs collected in formalin for diagnostic studies; spleen, liver, and lymph nodes should be collected frozen for virus isolation. Classic histopathology is often useful in suspecting yellow fever, Rift Valley fever, or a filovirus infection and in diagnosing some of the confounding diseases. Immunohistochemistry on fixed tissues can usually make a definitive diagnosis possible. Precautions appropriate to each virus should be taken to prevent infection while processing samples or performing a necropsy. Frozen samples should be appropriately packed and, whenever possible, shipped on dry ice, although diagnoses can sometimes be made on mishandled specimens. The receiving laboratory should be advised of the shipment, its estimated time of arrival, and the waybill number to allow for tracing the materials if, as

often happens, there is a delay en route. Diagnostic expertise and consultation are available from several laboratories.

## TREATMENT AND PREVENTION

Approaches to the prevention and treatment of the viral HFs vary with the infecting virus (Table 65-5). Barrier nursing and avoidance of parenteral exposures of hospital staff are important in management of all these diseases, but they are particularly important in Crimean-Congo HF and the filovirus diseases because of the regularity with which nosocomial transmission has been seen. The general principles of therapy are similar for all the HFs and require rapid atraumatic hospitalization, careful maintenance of fluid balance to avoid overhydration in the face of fragile systemic and pulmonary capillary beds, as well as probable myocardial compromise, management of the bleeding diathesis according to the usual principles, and the specific therapy appropriate to each disease (see Table 65-5). It is extremely important to exclude or empirically treat the conditions that may be most

Table 65-5 Prevention and Treatment of Viral Hemorrhagic Fevers

Disease	Prevention	Treatment
Arenaviridae Argentine HF	Safe, effective vaccine used for high-risk residents of endemic area.	Infusion of convalescent plasma during first 8 days of illness reduces mortality from 15%–30% to <1%.
Bolivian HF	Elimination of specific reservoir rodents from towns practical and effective; sporadic cases due to exposure outside towns, person-to-person transmission in families and institutions cannot be prevented; Argentine HF vaccine protects experimental animals against Bolivian virus.	Ribavirin likely to be effective and should be used in this and other arenavirus diseases unless proven effective alternative therapy available.
Lassa fever	None; intensive village-based rodent control may reduce risk.	Ribavirin effective in reducing mortality; use in higher risk patients, e.g., if aspartate transaminase >150 U/L.
Bunyaviridae Rift Valley fever	Vaccination of domestic livestock prevents epizootics/epidemics but not sporadic, endemic infections of humans; human vaccine safe and effective but limited supply; veterinarians and virology workers in sub-Saharan Africa candidates for vaccine.	Ribavirin and antibody therapy should be tried in HF patients based on studies in experimental animals.
Crimean-Congo HF	Tick avoidance; no slaughter of acutely infected animals (healthy but viremic and therefore an undetected threat); barrier nursing of suspected patients particularly important.	Ribavirin should be used based on in vitro sensitivity and on uncontrolled South African experience.
HF with renal syndrome (HFRS)	Rodent control and avoidance impractical in most cases; investigational vaccines deserve further evaluation.	Early diagnosis and supportive care lifesaving; ribavirin has positive effect during initial 4 days illness and should be used in severe HFRS if available.
Hantavirus pulmonary syndrome	Rodent avoidance useful; care should be taken before entering or cleaning closed buildings with potential rodent infestations.	Early diagnosis and supportive care potentially lifesaving; avoidance of hypoxia and excessive hydration coupled with careful management of shock.
Filoviridae Ebola/Marburg HF	Barrier nursing and needle sterilization in African hospitals particularly important; avoid close contact with suspected patients; do careful evaluation of sick nonhuman primates.	None other than supportive, which may be of limited utility; antiviral therapies urgently needed.
Flaviviridae Yellow fever	Vaccine is probably the safest and most effective in the world; control of <i>Aedes aegypti</i> would eliminate urban transmission but sylvatic transmission remains.	None other than supportive.
Dengue HF	Reduction of dengue transmission by <i>A. aegypti</i> control; investigational vaccines will probably be available soon; possibly useful in travelers but may be limited in solving hyperendemic dengue transmission that leads to dengue HF.	Supportive care effective and greatly reduces mortality.
Tick-borne flaviviruses	Avoidance of ticks; vaccination; postexposure prophylaxis with virus-specific IgG.	Supportive care.

HF, Hemorrhagic fever.

important in the differential diagnosis, particularly malaria, rickettsial infections, leptospirosis, relapsing fever, typhoid, and shigellosis.

### INTRODUCTION

Arenaviruses are rodent-borne pathogens that are important causes of hemorrhagic fever (HF) in Africa and South America. Lymphocytic choriomeningitis (LCM) virus occurs in Europe, the Americas, and elsewhere, causing febrile disease, sometimes with central nervous system (CNS) involvement, and congenital infections. Several South American viruses result in HF, but the geographic distribution of each disease is limited. In Africa, the only identified HF is Lassa fever, found only in West Africa. There are many arenaviruses in Africa and the Americas that are not associated with human disease. Arenaviruses cause chronic, inapparent infections of their rodent host, sometimes with prolonged or lifelong viremia and vertical transmission. Human epidemiology is determined by the distribution of infected rodents and their contact with humans, although in some cases interhuman infection has occurred. Thus these diseases occur in rural environments where humans and rodents come into particularly close contact. Their aerosol infectivity and stability have put them in the first rank of bioterrorist threats.<sup>1</sup> Overt cell damage by arenaviruses is minimal or modest, but they alter cell function and induce mediators of shock, directly or by immunopathologic mechanisms. They are sensitive to the antiviral drug ribavirin, and there is a safe, effective vaccine against Argentine HF.

### AGENTS

There are currently 20 recognized members of the *Arenaviridae*. They are shown in Figure 66-1 along with their known distribution and putative hosts. Their associated diseases are described in Table 66-1.

### Virion Morphology and Structure

Arenaviruses derive their name from the Latin *arenosus* (sandy) from the granular or sandy appearance of virions when viewed by thin-section electron microscopy.<sup>2</sup> Virions are spherical to pleomorphic, have a mean diameter of 110 nm to

130 nm (range 50–300 nm), and are enveloped in a lipid bilayer derived from cell membranes (Fig. 66-2). Embedded in the lipid bilayer are club-shaped projections, 8 nm to 10 nm in length, which are composed of the viral glycoproteins, GP1 (molecular weight, 40–64 kD) and GP2 (35–44 kD).<sup>3</sup> A GP1 tetramer forms the head of the spike, whereas a GP2 tetramer forms the stalk.<sup>4</sup> GP1 and GP2 are derived by posttranslational cleavage of a precursor molecule, GPC. The most abundant viral protein is the nucleoprotein, NP (63–78 kD), which associates with genomic RNA in circular nucleocapsid structures.<sup>3,5</sup> The viral L protein (200–250 kD) has transcriptase and replicase activity and is a minor component of nucleocapsids.<sup>6,7</sup> The Z protein (10–14 kD) is a small structural protein with a zinc-binding domain (RING finger motif).<sup>8,9</sup> By interacting with the viral polymerase, it inhibits transcription and replication.<sup>10</sup> Furthermore, it serves as a counterpart of the matrix protein found in other negative sense RNA viruses and is necessary for the generation of virus-like particles.<sup>11</sup> The electron-dense granules that give arenaviruses their sandy appearance have been identified as host cell ribosomes.<sup>3</sup> The function of these ribosomes has yet to be determined.

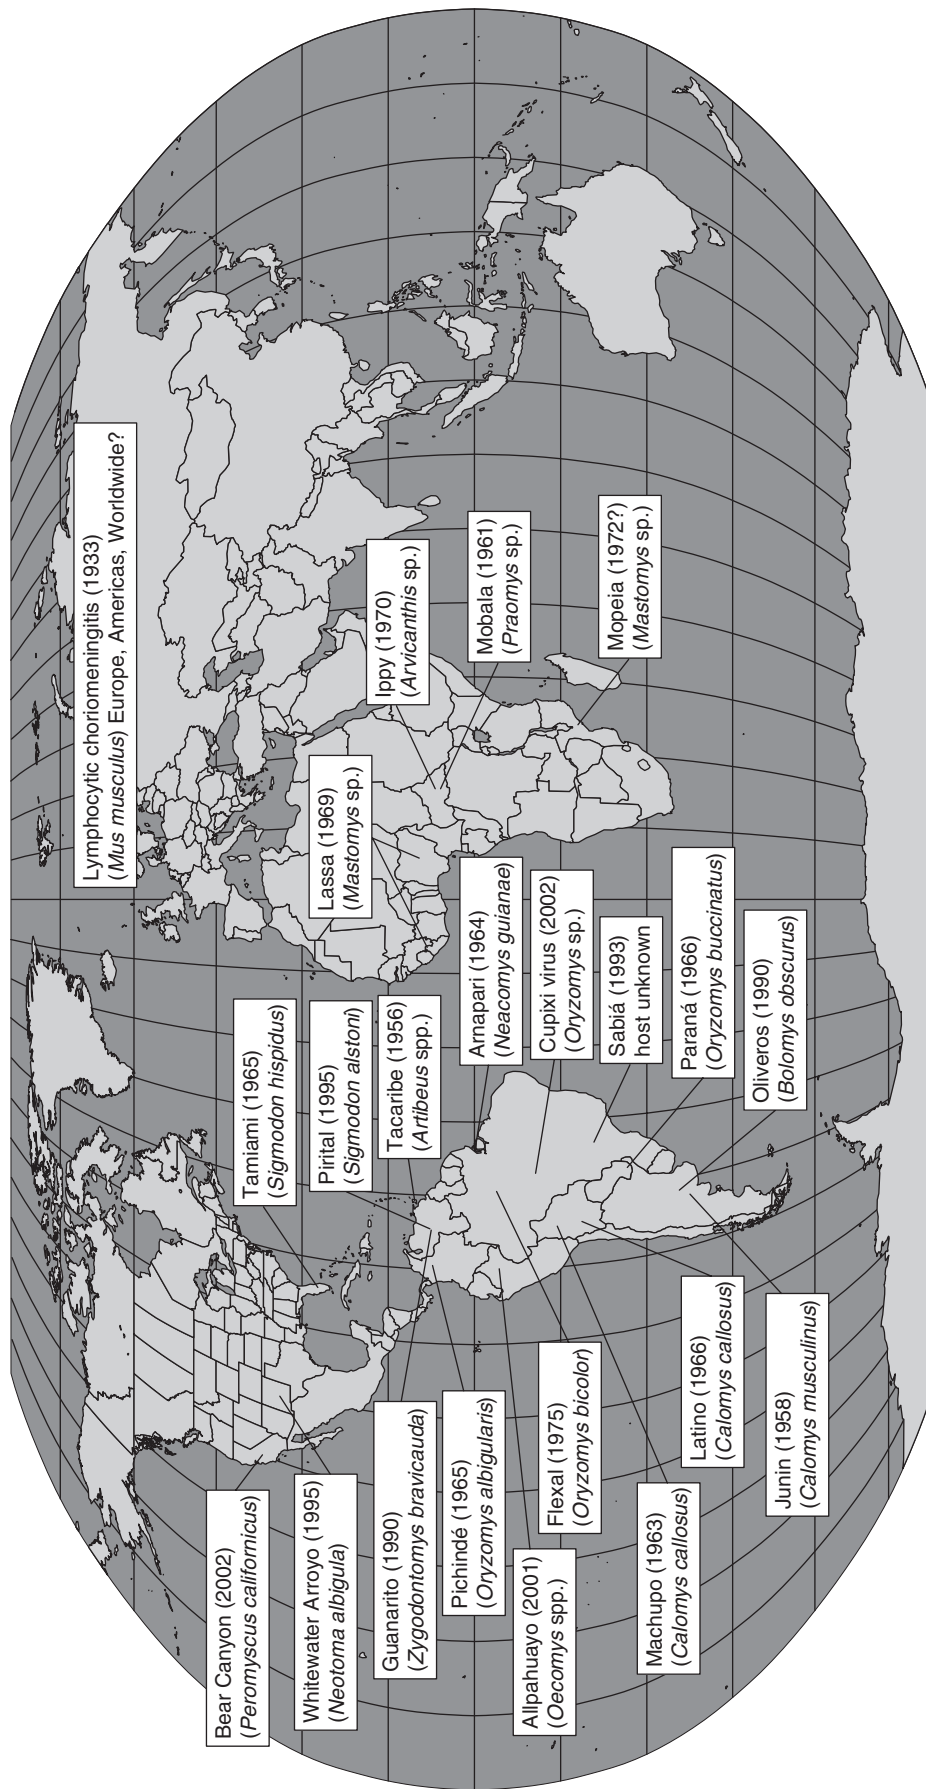

The lipid envelope of arenavirions makes them susceptible to organic solvents and detergents. Virus infectivity can also be inactivated by exposure to temperatures above 55°C, acidic or basic pH, ultraviolet light, and gamma irradiation.<sup>12</sup> Disinfectants containing phenolic compounds, hypochlorite, or quaternary amines effectively inactivate arenaviruses.<sup>13</sup>

### Genomic Organization

The arenavirus genome consists of two single-stranded RNA molecules designated S (small) and L (large), the lengths of which are approximately 3.4 kb and 7.2 kb, respectively. Two genes are encoded on each RNA in an ambisense orientation. The NP gene is encoded at the 3' end of the S RNA in the complementary sense, whereas the glycoprotein precursor (GPC) gene is encoded at the 5' end of the S RNA in message sense. In a similar manner, the L protein is encoded at the 3' end of the L RNA and the Z protein gene is found at the 5' end of the L RNA. The 19 nucleotides at the 3' end of each genomic segment are similar in all arenaviruses and are partial inverted complements to the 19 nucleotides at the 5' end of each RNA. This sequence complementarity allows genomic RNAs to form a circular conformation with short base paired "panhandle" structures necessary for efficient RNA synthesis.<sup>14</sup> The conserved sequences at the ends of each genomic RNA speculatively function as a binding site for the L protein. The genes on each viral RNA segment are separated by noncoding intergenic regions in both S and L segments. These intergenic regions have the potential to form several distinct stem-loop structures that are thought to play a role in transcriptional termination.<sup>5</sup>

### Replication

Arenaviruses gain entry into cells by attachment of the GP1 glycoprotein to one or more cellular receptors. One of these has been partially characterized as a 120- to 140-kD protein (alpha dystroglycan) found on primate and rodent cells.<sup>15</sup> Virus is then taken into large, smooth-walled vesicles where, in an acid environment, the GP2 glycoprotein mediates

**FIGURE 66-1** Recognized arenaviruses and their geographic distribution. Reservoirs are shown below the viruses in *italics*.

**Table 66-1** *Arenaviruses and Their Diseases*

Virus	Disease	Clinical Manifestations
<b>New World Viruses or Tacaribe Complex</b>		
Junin	Argentine HF	Severe systemic disease with hemorrhage, prominent neurologic manifestations
Machupo	Bolivian HF	Resembles Argentine HF
Guanarito	Venezuelan HF	Resembles Argentine HF
Sabia	—	Limited experience suggests resemblance to Argentine HF but one case with prominent liver necrosis as well
Flexal	—	Two symptomatic laboratory infections observed; disease spectrum not defined
Pichinde	—	Asymptomatic
Amapari, Pirital, and others	—	Human infections not yet identified, pathogenicity unknown
<b>Old World Viruses</b>		
LCM	LCM	Acute febrile illness with thrombocytopenia and leukopenia; sometimes associated with orchitis; aseptic meningitis often follows the initial febrile period
Lassa	Lassa fever	Encephalitis rarely occurs; maternal infection may result in fetal hydrocephalus and chorioretinitis
Mopeia, Mobala	—	Severe systemic illness; hemorrhagic manifestations or neurologic involvement sometimes seen
Unnamed new isolates	—	Human infection never observed, but laboratory animal studies suggest less pathogenic than Lassa virus
		Human infection never observed

HF, hemorrhagic fever; LCM, lymphocytic choriomeningitis.

fusion between the virion membrane and the endosomal membrane. This process releases nucleocapsids into the cytoplasm where replication takes place.<sup>5</sup>

The ambisense arrangement of arenavirus genes appears to provide a unique mechanism for regulating gene transcription, with genes lying at the 3' end of each genomic vRNA (i.e., NP, L) being expressed first. Genes residing at the 5' end

of each genomic segment (i.e., GPC, Z) cannot be expressed in the absence of protein synthesis.<sup>16</sup> To initiate gene expression, the viral L protein, which has RNA-dependent RNA polymerase activity and possibly endonuclease activity, is thought to cleave the cap and one to seven bases from cellular messenger RNAs (mRNAs) and use these primers to initiate transcription of subgenomic mRNAs ("cap snatching").<sup>17,18</sup>

**FIGURE 66-2** Electron micrograph of Machupo virions. Glycoprotein spikes (GP) are embedded in the virion membrane (VM). Electron-dense ribosomes (R) are present in the interior of the virions. A virion budding from a cell membrane (BV) is visible. (Courtesy of C. Goldsmith, Atlanta, GA; S. Zaki, Atlanta, GA; and F. Murphy, Davis, CA.)

These mRNAs, which are not polyadenylated, are then translated by host cell ribosomes to produce NP and L proteins.

Genes found at the 5' ends of genomic RNAs (i.e., GPC, Z) are not translated directly though they are in the proper coding sense. Viral genomic RNAs must go through the first stages of replication to obtain expression of these genes. In this process, the L protein is thought to initiate RNA replication using a dinucleotide template (pppGpC) rather than a capped primer and a full-length, genome-complementary RNA species termed an *antigenome* is transcribed.<sup>19</sup> Newly synthesized RNAs are assumed to associate with NP and L proteins in the cytoplasm to produce nucleocapsids.

The zinc finger protein was initially predicted from the L RNA genetic sequence.<sup>20</sup> It appears to bind to the promyelocyte leukemia protein,<sup>21</sup> but more fundamentally it is required for viral and messenger RNA synthesis<sup>22</sup> and participates in viral particle formation.<sup>23</sup> The protein serves as a matrix protein and interacts with the N protein, as well as driving particle formation.<sup>24</sup>

The GPC undergoes considerable processing that is only partially understood. After translation, GPC is truncated by cleavage of a signal peptide from the N-terminus, glycosylated, transported from the endoplasmic reticulum to the Golgi network, cleaved into GP1 and GP2, and transported to the plasma membrane where budding occurs<sup>4,25-27</sup> (see Fig. 66-2). The cytoplasmic tail of GP2 has been shown to interact with NP,<sup>28</sup> which, with the Z protein,<sup>24</sup> may play a critical role in assembly and budding.

## Virology

Arenaviruses can grow in a variety of cultured vertebrate cell lines including Vero, Vero E6, BHK-21, mouse L, pig kidney, rabbit kidney, human diploid, and HeLa cells.<sup>5</sup> In culture, arenavirus-infected cells usually appear normal. In some cell-virus combinations, cytopathic effect (CPE), characterized by cell rounding and detachment of cells from the culture vessel surface, can be observed. Different isolates of the same virus can differ in their ability to cause CPE in culture. Arenaviruses are somewhat slow growing in cell culture and will form plaques in 4 to 9 days when grown under a semisolid medium containing a vital stain such as neutral red.

Laboratory animal systems for isolating and propagating arenaviruses include mice, hamsters, and guinea pigs. Pathogenicity varies among viruses and can also differ among strains of the same virus. For example, low-passage isolates of Junin virus differ in their pathogenicity for guinea pigs and nonhuman primates.<sup>29,30</sup> In addition, the age of the animal host, host genotype, and the route of inoculation affect the outcome of infection.<sup>31</sup> New World arenaviruses are generally nonpathogenic for adult mice but may cause an immunopathologic encephalitis after intracranial inoculation of weanling or newborn mice.<sup>32-34</sup> All New World arenaviruses are pathogenic for suckling hamsters.<sup>35</sup>

Of the animal models using Old World arenaviruses, the infection process of LCM virus in mice has been the most intensively studied. Adult mice inoculated intracerebrally with LCM virus develop fatal, immune-mediated choriomeningitis whereas intraperitoneal inoculation results in an immunizing infection with viral clearance<sup>36</sup> (reviewed in Buchmeier and colleagues<sup>5</sup>). Suckling mice or immunosuppressed adults,

on the other hand, develop a lifelong, persistent infection after inoculation, as do immunocompetent adults infected with the immunosuppressive CI-13 strain of LCM virus.<sup>37,38</sup> With most LCM virus–mouse strain combinations, there is no acute disease in the newborn mouse, even after intracerebral inoculation, but chronic immune complex renal disease may develop if host-virus genetics results in antibody formation.<sup>39</sup> In mice and guinea pigs, the pathogenicity of other Old World arenaviruses is more variable, with the outcome of infection depending highly upon host genotype and virus strain.<sup>31</sup>

## Persistence and Defective Interfering Virus

In natural rodent hosts, as well as in cell culture, arenavirus infections can shift from an acute phase, in which there is active viral replication and virus production, to a persistent phase characterized by a reduction in the amount of infectious virus produced. In persistent infection, most cells remain infected for life, and there are alterations in transcription, replication, and expression of viral proteins. In cell cultures, a small population of cells may be transiently infected, providing a constant pool of cells for reinfection.<sup>40</sup> A reduction in expression of the viral glycoproteins has been observed in cultured cells and mice persistently infected with LCM virus.<sup>41,42</sup> In persistently infected cells, there is an increase in the number of S genomic RNAs relative to the number of L genomic RNAs.<sup>43</sup> In addition, increased levels of NP mRNA can be detected, as well as populations of subgenomic-length fragments of genomes and antigenomes.<sup>43-46</sup>

Even in the absence of CPE, arenavirus infections can impair normal cellular functions. Infection of murine endocrine cells with LCM virus decreases levels of growth hormone and thyroid hormone production.<sup>47,48</sup> This viral perturbation of cellular physiology appears to be selective for “luxury” functions, but “housekeeping” functions appear to be minimally affected.<sup>48</sup>

Defective interfering (DI) virus, which is able to interfere with the infectivity of standard virus, is produced during acute and persistent arenavirus infections. When LCM virus stocks are passed at high multiplicity of infection in cell culture, the titer of infectious virus has been shown to rise and fall with passage.<sup>3</sup> Peak titers can exceed trough titers by more than 1000-fold. This interference effect is presumably due to increased production of DI virus after high-titer inoculation, which competes with standard virus for viral packaging proteins in the subsequent passage. Infection of cultured cells with DI virus prior to challenge with standard LCM virus inhibits the replication of the standard virus.<sup>49</sup> Concurrent intracranial injection of DI virus with standard LCM virus inhibits cerebellar disease in a suckling rat model.<sup>49</sup> The potential participation of DI virus in establishing or maintaining chronic infections or in recovery from acute infections in vivo have yet to be established.

## Antigenic and Genetic Relationships of Arenaviruses

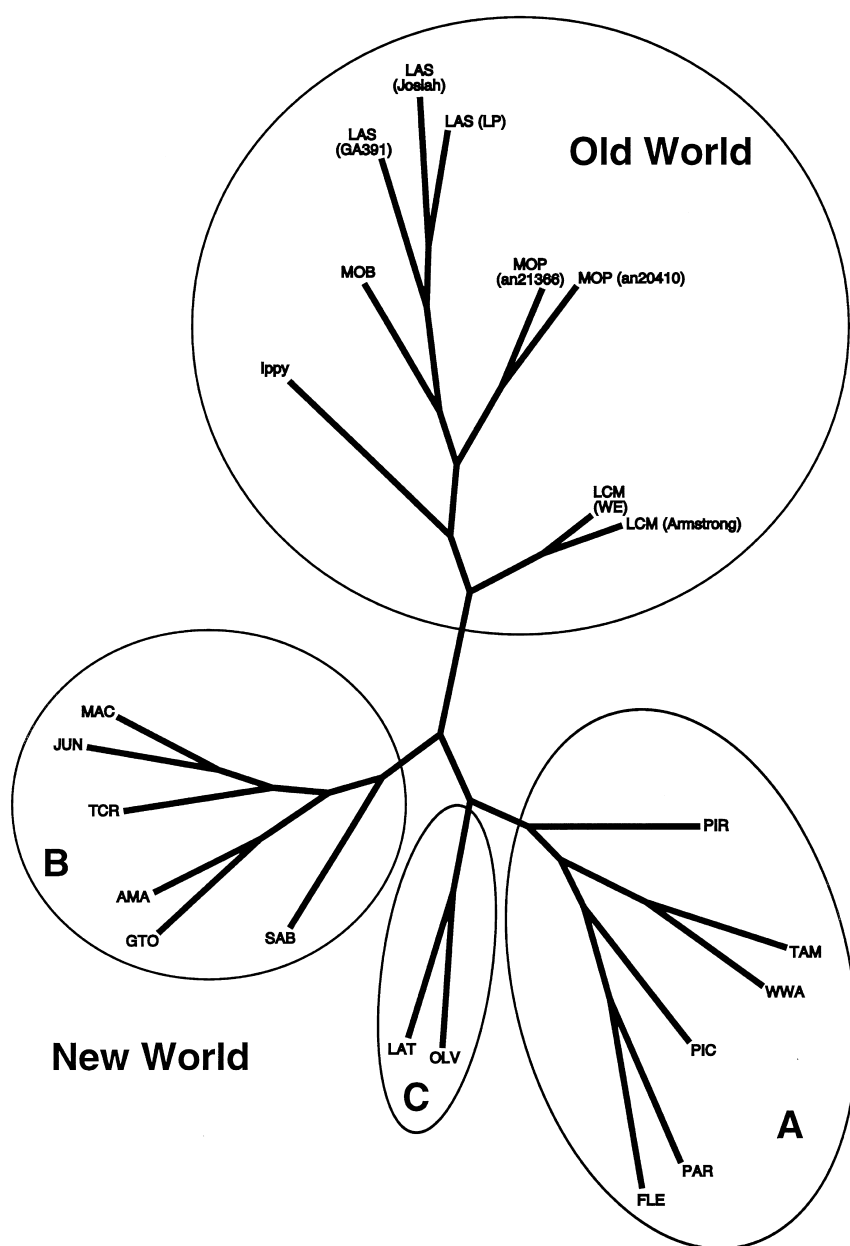

Serologic assays, primarily the complement fixation (CF) test, indirect immunofluorescent antibody (IFA) test, neutralization assay, and enzyme-linked immunosorbent assay (ELISA), have been used to define the antigenic relationships

of viruses within the Arenaviridae.<sup>50–55</sup> The CF and IFA tests, which primarily recognize epitopes present on the NP, were first used to divide the arenaviruses into two groups, the Old World group and the New World group or Tacaribe complex, and disclosed that there is low-level antigenic relatedness between the two groups.<sup>51,53</sup>

More refined IFA, ELISA, and neutralization tests further defined relationships among arenaviruses. Studies using monoclonal antibodies showed that epitopes on NP and GP2 are shared by Old World and New World arenaviruses<sup>56,57</sup> and demonstrated close antigenic relationships among Amapari, Junin, Machupo, and Tacaribe viruses and among Pichinde, Parana, and Tamiami viruses.<sup>54,58,59</sup> Within the Old World arenaviruses, Ippy, Lassa, Mobala, and Mopeia share certain

antigenic determinants that distinguish the African arenaviruses from LCM virus.<sup>53,57,60,61</sup>

Analysis of genetic sequence data has provided the most complete picture of arenavirus relationships. New World arenaviruses comprise three evolutionary lineages that are designated lineages A, B, and C<sup>62</sup> (Fig. 66-3). Within the New World arenaviruses, lineage A contains Flexal, Parana, Pichinde, Pirital, Tamiami, and Whitewater Arroyo viruses. Lineage B contains the four agents of arenaviral HF in the New World—Guanarito, Junin, Machupo, and Sabia, as well as Amapari and Tacaribe viruses. Latino and Oliveros viruses compose lineage C. Among the Old World arenaviruses, LCM virus is most closely related to the New World arenaviruses. Ippy virus occupies an intermediate position, whereas Mobala,

**FIGURE 66-3** Dendrogram showing phylogenetic relationships of the arenaviruses. The Old World group and three lineages within the New World are circled. Parentheses indicate strain designations. Three different strains of Lassa virus, two different strains of Mopeia virus, and two different strains of LCM virus are included to illustrate sequence diversity among strains of the same virus. AMA, Amapari virus; FLE, Flexal virus; GTO, Guanarito virus; JUN, Junin virus; LAS, Lassa virus; LAT, Latino virus; LCM, lymphocytic choriomeningitis virus; MAC, Machupo virus; MOB, Mobala virus; MOP, Mopeia virus; OLV, Oliveros virus; PAR, Parana virus; PIC, Pichinde virus; PIR, Pirital virus; SAB, Sabia virus; TAM, Tamiami virus; TCR, Tacaribe virus; WWA, Whitewater Arroyo virus.

Mopeia, and Lassa viruses make up the most distantly related group. Considerable sequence diversity, up to 25% nucleotide divergence, is observed among Lassa virus strains and some divergence is evident among Mopeia virus strains and strains of LCM virus. Thus the relationships established by antigenic characterization are confirmed and further refined by analysis of genetic sequence data.

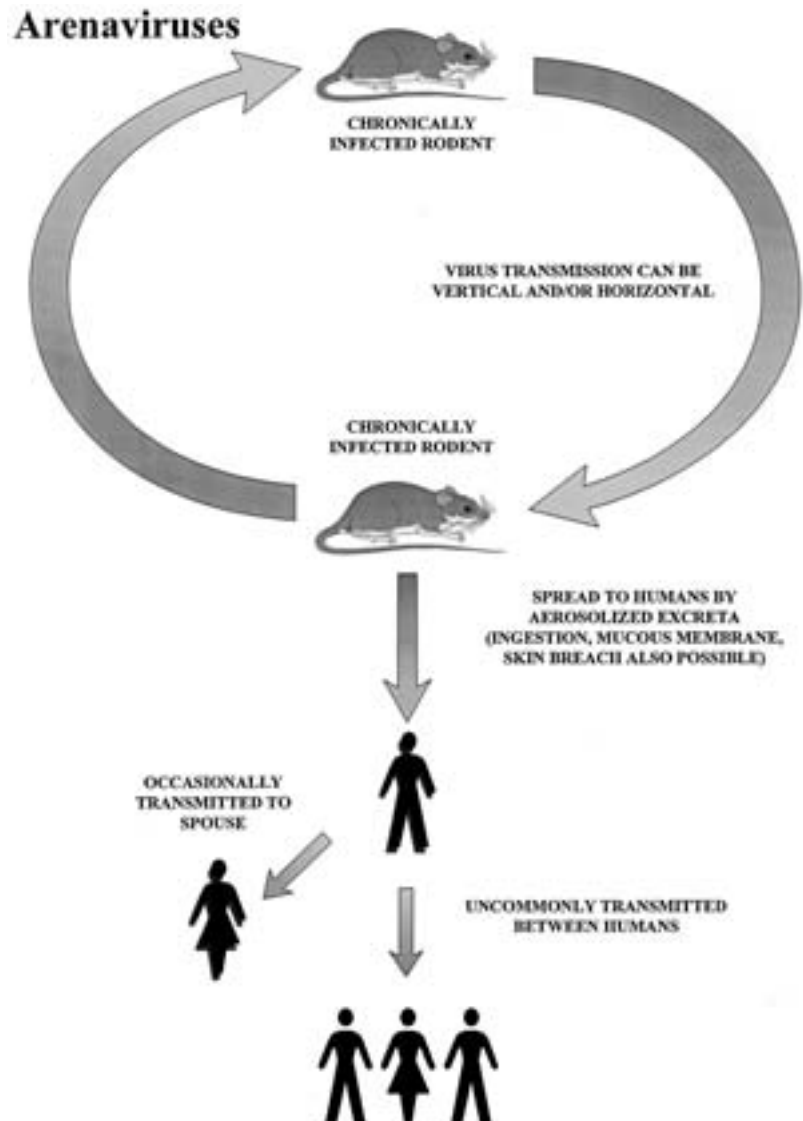

## EPIDEMIOLOGY

### Transmission Cycle

A hallmark of the Arenaviridae is the specificity of the host-virus relationship and the chronic, inapparent infection of the rodent host (Fig. 66-4). The Old World arenaviruses are associated with rodents of the family Muridae, subfamily Murinae (Old World rats and mice) and the New World viruses with the subfamily Sigmodontinae (New World rats and mice). This specific host-virus association appears to be a highly evolved form of parasitism, which may be the result of

thousands of years of coevolution between each virus and its established rodent host species.<sup>63</sup> Maintenance of infection within reservoir populations may be via horizontal or vertical routes.<sup>64</sup> The chronically infected host is usually asymptomatic and shows normal growth, behavior, and intraspecific interactions. As it moves through its environment and contacts other animals, the infected host may shed large quantities of virus in urine, feces, and saliva. Shed virus may be infectious to other animals via aerosolization.<sup>65,66</sup> Venereal transmission between rodents may be highly efficient in some cases.<sup>67</sup> Transmission by bite, especially between adult males, may also be an important mechanism maintaining virus within reservoir populations.<sup>68</sup> However, the most important mechanism of virus perpetration in some virus-host combinations is vertical transmission.<sup>64,67,69-73</sup>

The actual mechanism of human infection from rodents is unknown. There is quite strong evidence that these viruses are aerosol-infectious and that they readily spread from rodents to humans by this route. Aerosols of LCM,<sup>74</sup> Lassa,<sup>75</sup> and Junin<sup>76</sup> viruses are all stable and infectious to

**FIGURE 66-4** Transmission cycle of arenaviruses. These viruses chronically infect rodents. In some rodent-virus combinations there is lifelong viremia, and vertical transmission is very important in maintenance; in others, chronic virus shedding without persistent viremia occurs, or more complicated patterns are seen (see Childs and Peters<sup>64</sup>). In any case, humans are a deadend host except in rare situations.

nonhuman primates. In addition, several studies clearly implicate aerosols as one route of human infection.<sup>77–79</sup> It is very likely that rodents shedding urine generate primary aerosols that are inhaled by humans to provide the major source of arenavirus disease. The survival of arenaviruses in rodent urine will be markedly affected by the pH (diet) and other components, particularly protein (some rodent species normally have proteins present in urine).

Other routes of human contamination are less likely but cannot be excluded. Although virus is readily detected in rodent throat swabs and feces, the quantity of virus output is much less, and the mechanisms that would generate aerosols are less apparent. Secondary aerosol generation is notoriously inefficient so disturbing shed urine is also a less likely source of infection. Conjunctival or other mucous membranes, ingestion, and occult cuts are possible routes of entry but similarly are less likely given the relative susceptibility to inactivation of arenaviruses in the environment, although virus survival in the dried state is not well-defined. Oral infection, perhaps with a gastric portal, has clearly been demonstrated in the mouse,<sup>80</sup> and it is well-known that the arenaviruses are highly infectious on scarified skin.<sup>81</sup> In some circumstances, humans may come into direct contact with reservoir rodents (see later Lassa fever discussion) and be intensively exposed by several routes.

## Geography

The distribution of each arenavirus is limited to that of its rodent host, but it is often less than the range of the host, particularly in the Americas (see Fig. 66-1). Within endemic areas, infection in host populations is often highly focal, and antibody prevalences in host populations vary considerably in both time and space. Factors in emergence are poorly understood, but one common theme with Bolivian<sup>82</sup> and Venezuelan HF<sup>83</sup> has been conversion of forest to cultivated fields, which has often resulted in “new” arenavirus diseases from viruses of the colonizing savanna rodents infecting humans. The human risk is particularly high if the rodent species enters towns and houses. Cleared forest areas in Africa are also at risk of Lassa fever from savanna-adapted reservoirs.

Argentine HF occurs in the humid pampas, the most fertile area of a country, which depends on agriculture for its

prosperity. The Argentine HF–endemic area includes only a part of the geographic range of the primary host species, the drylands vesper mouse (*Calomys musculinus*), which is common and widely distributed in central and northwestern Argentina.<sup>84</sup> A striking epidemiologic characteristic of Argentine HF is the steady and progressive geographic extension that occurred rapidly in the years after its discovery and has continued until the present.<sup>85</sup> In 1958, cases were limited to an area of approximately 16,000 km<sup>2</sup>, with the population at risk estimated to be 270,000 persons. At present, the endemoepidemic region covers an area of approximately 150,000 km<sup>2</sup>,<sup>86</sup> where an estimated 3 million people live. The incidence of Argentine HF is not the same in different areas of the pampas or in different years. In general, it is higher during a period of 5 to 10 years in the newly involved areas, and it later declines. Geographic extensions in the last decade have been smaller than those seen earlier.

Nevertheless, there is some continuing northward extension, as well as a reemergence in historical areas that have not reported clinical disease in the last 10 years.<sup>87</sup> The disease is both dramatic and characteristic so it is likely that the patterns based on clinical disease (confirmed by laboratory means after 1965; Fig. 66-5) do indeed represent a valid measure of virus activity, particularly when the results of virologic data on rodents are considered.<sup>68</sup> The elucidation of the factors behind the spread of Argentine HF is the most important problem confronting our understanding of the epidemiology of arenavirus disease.

Bolivian HF is restricted to the Beni department of Bolivia, although the range of *C. callosus* is much wider, including northern Argentina and Paraguay, through eastern Bolivia to east-central Brazil.<sup>88</sup> Recent evidence suggests that this discrepancy may be explained, at least in part, by improvements in our understanding of the taxonomy of *Calomys*. The reservoir for Machupo virus appears to be a distinct species of *Calomys*, but not *C. callosus*, with a more restricted distribution.<sup>89</sup>

Venezuelan HF has been restricted to the municipality of Guanarito, in the southern tip of Portuguesa state, on the Venezuelan llanos.<sup>83</sup> The reservoir of Guanarito virus, *Zygodontomys brevicauda*, is a savanna species found from southeastern Costa Rica through Brazil north of the Amazon.<sup>88</sup> Recent surveys<sup>90</sup> have demonstrated the presence

**FIGURE 66-5** Annual cases of Argentine hemorrhagic fever showing the decline in cases with vaccination of the critical at-risk adult population. After 1965, laboratory confirmation of cases began and, after 1977, the Instituto Nacional de Enfermedades Virales Humanas was responsible for laboratory confirmation of all cases with samples submitted.

of Guanarito virus genotypes (some closely matching genotypes from case patients in the disease-endemic area) in host populations over a wide area of the Venezuelan llanos, including areas in five states up to several hundred kilometers from the disease-endemic area.

Lassa fever is a West African disease. The countries most often associated with it are Sierra Leone, Guinea, Liberia, and Nigeria. The extent of Lassa fever transmission in the intervening countries is not known with certainty, but there is evidence to suggest its presence in Côte d'Ivoire, Burkina Faso, and Senegal.<sup>91-93</sup> This broad geographic distribution in an area that enjoys considerable tourism from the United Kingdom and other developed areas make Lassa fever the most exported of the viral hemorrhagic fevers.<sup>94</sup> Lassa virus is carried by rodents of the *Mastomys* species complex.<sup>95,96</sup> At least eight species occur in Africa south of the Sahara, and their systematics and distribution are complex and poorly understood.<sup>97</sup> Two species of multimammate rats are frequently associated with Lassa virus infection. Although morphologically very similar, *Mastomys huberti* and *Mastomys erythroleucus* are distinguished by karyotyping. *M. huberti*, the 32-chromosome species, tends to be found in houses and villages; *M. erythroleucus* has 38 chromosomes and is found more frequently in "bush" areas.<sup>98,99</sup> Although infection in *Mastomys* populations is focal, both species may have a high prevalence of antibody (near 30%).<sup>96</sup>

Several other Old World arenaviruses are known from African rodents (see Table 66-1 and Fig. 66-3), but their distribution and pathogenicity for humans are not understood. It seems likely that with further research the patterns seen with the several African viruses will come to resemble those of their American relatives.

LCM virus has a broad distribution wherever the common house mouse (*Mus musculus*) is found, including Europe, the Americas, Australia, and Japan.<sup>69,100-104</sup> Both *Mus m. domesticus* and *M. m. musculus* have yielded virus. The phylogenetic relationships of the viruses and the possible infection of other subspecies of *Mus* are unknown.

## Transmission to Humans

### Argentine Hemorrhagic Fever

Epidemics occur predominantly during the major harvesting season in Argentina, with a peak incidence in the month of May. The disease is four times as prevalent in males as in females, and is more prevalent among rural workers than in urban populations. Children under 14 years of age constitute about 10% of cases annually, but disease is uncommon in those less than 4 years old and exceptional in those less than 2 years of age. The seasonal distribution of the illness and the prevalence in male rural workers reflect occupational exposure of humans and the habits of the rodent host of Junin virus. Annual incidence within the endemic area may be as low as 1 in 100,000, but in the areas of highest activity it reaches 140 per 100,000 population and 355 per 100,000 adult males.

The Argentine HF endemic area is largely a patchwork of crop fields, which is crisscrossed by linear islands of relatively stable border habitats (roadsides, fence lines, and railroad rights of way). The primary host for Junin virus, the drylands

vesper mouse (*C. musculus*), is a habitat generalist.<sup>105</sup> Although it is most frequently captured in stable border habitats, it ventures into mature and postharvest crop fields where it supplements its diet with grain from corn and soybeans.<sup>106</sup> The drylands vesper mouse is rarely captured in or around human dwellings, although it may enter parklands and undeveloped areas adjacent to the surrounding pampas. In the early years of Argentine HF, the men affected worked in close contact with the land and harvested crops by hand. Later, mechanized agricultural practices became common, but the workers in the field, especially tractor drivers, have continued to become infected. Cases may be associated with the inhalation of infectious aerosols generated during the mechanized harvesting process, or with exposure to primary aerosols of rodent urine or contact with contaminated nesting materials in border habitats. The annual incidence of Argentine HF is positively correlated with local population densities of the reservoir.<sup>107</sup> This epidemiologic pattern is being further modified through vaccination of high-risk populations (see Fig. 66-5).

Argentine HF is not usually contagious, although person-to-person transmission can occur. A special situation is represented by a small number of women who are thought to have acquired the disease from their convalescent spouses through intimate contact.<sup>108</sup>

### Bolivian Hemorrhagic Fever

The reservoir for Machupo virus is a species of the genus *Calomys* closely related but not identical to *C. callosus*. The host species resides in habitats where grassland intergrades into forest and, unlike *C. musculus*, thrives in villages and near human habitations, which are found on high ground in seasonally inundated areas of the Beni Department. Bolivian HF tends to be a seasonal disease, with more cases occurring in the dry season, at the peak of agricultural activity. Most sporadic cases have involved adult men in rural areas, probably via contact with the rodent host in agricultural settings or in isolated small cottages.

However, family and community clusters of Bolivian HF cases affecting both sexes and all age groups have been centered around towns or hospitals. Epidemics in towns may occur during epizootic conditions when rodent densities reach unusually high levels and rodents invade towns or villages. In 1963-1964, a Bolivian HF epidemic occurred in the village of San Joaquin that resulted in 637 cases and 113 deaths among the town's 3000 residents.<sup>82</sup> The outbreak ended abruptly after two weeks of continuous trapping in homes, during which 3000 *C. callosus* rodents were captured.<sup>109</sup> Transmission to humans under these conditions is likely from inhalation of infectious aerosols concentrated within confined spaces of houses and outbuildings, but direct contact of broken skin or mucous membranes with rodent excreta or contaminated fomites such as food is also a consideration.

Person-to-person transmission, likely via direct contact with infectious body fluids, may occur in familial or nosocomial settings. For example, five health-care workers who were exposed to the index case or a secondary case contracted Bolivian HF in a hospital in Cochabamba in 1971,<sup>110</sup> and in 1994 a farm worker transmitted fatal Bolivian HF to six of

eight family members.<sup>111</sup> Transmission by intimate contact during convalescence is also possible.<sup>112</sup>

### Venezuelan Hemorrhagic Fever

In 1989, a severe HF was recognized by clinicians in the municipality of Guanarito, Guanarito State, Venezuela. At first, efforts toward laboratory diagnosis centered on dengue viruses, but the causative agent was soon isolated, shown to be an arenavirus, and named Guanarito virus.<sup>113</sup> Guanarito virus is specifically associated with *Z. brevicauda*, while a second arenavirus, Pirital virus, is associated with co-occurring *S. alstoni*.<sup>114</sup> Within the Venezuelan HF endemic area, both rodent species are commonly captured in crop fields, borders, and roadside habitats, and they are only rarely captured in the peridomestic environment.

While cases have been observed throughout the year, epidemics appear to have a seasonal peak in November to January, coinciding with maximum agricultural activity in the endemic region. Although children and adults of both sexes suffer disease, the highest risk is among adult male agricultural workers.<sup>83</sup> Thus transmission to humans likely occurs most frequently outside the home and may be related to agricultural activities. Person-to-person transmission or nosocomial infection has not been observed in spite of the fact that Venezuelan HF patients, like other South American HF patients, are usually admitted to open wards with minimal isolation precautions.

### Lymphocytic Choriomeningitis

The natural rodent reservoir of the virus is the cosmopolitan house mouse, *M. musculus*, although outbreaks of human disease have also been traced to pet hamsters (*Mesocricetus auratus*) in the United States,<sup>115</sup> Germany,<sup>102</sup> and France.<sup>116</sup> As its name implies, the house mouse is frequently found living in close association with humans within homes and other man-made structures in both rural and urban situations. Infection with LCM virus in house mouse populations can be highly focal. In inner-city Baltimore, antibody-positive mice were clustered within residential blocks<sup>117</sup>; infection varied from 0% (0/753) to 27% (214/594) of mice on four farms in California.<sup>118</sup>

The incidence of human disease peaks in the fall and winter, presumably reflecting the seasonal invasion of homes by mice. As expected, human disease is associated with the regional prevalence of mouse infection and can vary by region or even by house.<sup>102,119</sup> Risk of infection is higher among rural dwellers and, in the United States, in low-income groups.<sup>120</sup> Human seroprevalence to LCM virus has often been found to range from 5% to 10% in the United States and elsewhere.<sup>69,102,120,121</sup> An antibody survey using hospital patients in Birmingham, Alabama, showed a prevalence of IgG antibody to LCM virus that was much lower in younger patients than in patients over 30 years of age, although it was not known whether this represented a secular decrease in risk of infection in recent decades or a lesser risk in children.<sup>120</sup> The number of acute LCM cases annually is not known because diagnostic testing is not commonly performed; during the period 1941 to 1958, LCM was the confirmed diagnosis in about 10% of patients with febrile CNS disease admitted to a tertiary care hospital in Washington, D.C.<sup>122,123</sup>

### Lassa Fever

Lassa fever is an extremely common infection among adults in endemic areas of West Africa. In a heavily affected region such as Sierra Leone's Eastern Province, the disease may be responsible for more than one-fourth of medical admissions and of medical deaths.<sup>96</sup> In the same area it is also common among pediatric admissions.<sup>124</sup> Because of the similar incidence of disease among men and women and the frequent involvement of children, peridomestic exposure is likely to be important.<sup>125</sup> Indeed, rodent density may be higher in houses than in the surrounding agricultural or bush areas.<sup>96</sup> In this setting, transmission to humans may occur via inhalation of primary aerosols from rodent urine, by contact with contaminated fomites, or by ingestion of contaminated food. Human infection is also enhanced by the practice of hunting and consuming rodents as a food source, as well as the high levels of rodent infestation, open food storage, and closed shutters during the day—a practice that favors prolonged rodent activity.<sup>96</sup> These factors are exacerbated in the diamond-mining areas of Sierra Leone and during civil disruption. In Guinea, cases were clustered during the dry season and early part of the rainy season, coinciding with the period of maximum infection in *Mastomys* populations.<sup>73,125</sup>

Interhuman transmission of Lassa fever occurs but it is difficult to quantitate because of the frequent presence of infected *Mastomys* in houses.<sup>126</sup> At least one outbreak provided evidence of person-to-person transmission of Lassa virus without confounding infected rodents or reported needle use.<sup>127</sup> Although rare,<sup>128</sup> devastating hospital outbreaks have occurred and have been attributed to aerosols<sup>129</sup> or to lack of sterilization of parenteral injection equipment.<sup>130</sup>

### Maintenance of the Virus in Rodent Host Populations

#### Argentine Hemorrhagic Fever

Junin virus is likely maintained in *C. musculus* reservoir populations primarily via horizontal transmission. When transmitted vertically, the virus may have important deleterious effects on fitness. Newborn *C. musculus* infected with Junin virus in the laboratory have high mortality (70%), and survivors show stunting and greatly reduced fecundity.<sup>131</sup> Animals infected in the laboratory as adults showed a split response. Half of the animals developed antibody and cleared virus; the remainder had chronic viremia and persistent shedding of virus in urine and saliva; there was no obvious deleterious effect on these chronically infected adults.<sup>132</sup> Field studies of natural populations demonstrated that infection with Junin virus among wild *C. musculus* was more frequent among males than females and was positively correlated with age and the presence of wounds or scars.<sup>68</sup> These data suggest that aggressive encounters between adult males may be an important mechanism of transmission within reservoir populations.

#### Bolivian Hemorrhagic Fever

As with Junin virus, vertical transmission of Machupo virus would have a severe effect on host reproductive fitness of its reservoir rodent. In the laboratory, females inoculated at birth were chronically infected and sterile.<sup>133</sup> Also, as was later

shown to be the case with Junin virus and *C. musculus*, colonized *Calomys* rodents infected with Machupo virus as adults showed a split response: 50% of the animals developed antibody and cleared viral infection, while 50% showed chronic viremia and viruria. Longitudinal field studies are needed to assess the mechanisms of transmission of Machupo virus in natural populations.

### Venezuelan Hemorrhagic Fever

Laboratory experiments indicate that the maintenance pattern for Guanarito virus in *Z. brevicauda* may be different from either the Junin or Machupo models.<sup>134</sup> Newborn *Z. brevicauda* inoculated subcutaneously with Guanarito virus developed a chronic infection with persistent shedding of virus in urine and saliva. There was no detectable effect of infection on growth of these animals (after 3 weeks). Subcutaneous inoculation of adult animals resulted in a split response. Four of 12 animals showed only transient viremia, followed by the development of high-titer neutralizing and immunofluorescent antibody. The remainder showed chronic viremia and persistent shedding of virus in urine and saliva. Eleven females that had been inoculated with Guanarito virus as adults had only two apparently normal litters after being paired with males, while 11 sham-inoculated females had 10 litters. Thus, horizontal transmission of virus has an apparent negative effect on reproductive fitness. The presence of virus in the blood of one of three pups born to an infected female indicates that vertical transmission is possible, but the fecundity of females infected as newborns has not been studied.<sup>135</sup>

### Lassa Fever and Lymphocytic Choriomeningitis

In contrast to the pattern with the New World arenaviruses, LCM and Lassa viruses are thought to be maintained by vertical transmission within reservoir populations. All pups born to chronically infected females are themselves chronically infected (perhaps transovarially).<sup>136</sup> Conversely, inoculation of adult hosts with LCM or Lassa virus results in an immunizing infection<sup>64,67,70,71</sup>; young born to immunized animals are also protected by maternal antibody. This pattern was observed in field studies of Lassa virus in Guinea; most animals trapped were naïve, or chronically infected, with only occasional antibody-positive rodents.<sup>73</sup> Thus, strict horizontal transmission of virus within host populations would likely result in its rapid extinction.

## DISEASES

### Clinical Manifestations

The South American HFs resemble one another, and Argentine HF is the best described. Lassa fever has a similar pathogenesis, but neurologic involvement, thrombocytopenia, leukopenia, and bleeding manifestations are less prominent.

### Argentine Hemorrhagic Fever

The incubation period is usually 6 to 14 days with outer limits of 4 to 21 days. The onset of illness is insidious, with chills, malaise, anorexia, headache, myalgias, and moderate hyperthermia (38°C to 39°C). After several days, this gives

way to further constitutional, gastrointestinal, neurologic, and cardiovascular signs and symptoms. Low backache, retro-orbital pain, nausea or vomiting, epigastric pain, photophobia, dizziness, and constipation or mild diarrhea are common symptoms. An almost constant absence of productive cough, sore throat, or nasal congestion is helpful in distinguishing the initial symptoms of Argentine HF from those of influenza or other acute respiratory infections.

During the first week of illness, physical examination reveals flushing of the face, neck, and upper chest. Conjunctival congestion and periorbital edema may also occur. The oropharyngeal membranes are congested, and there is congestion of the vessels bordering the gums, which may bleed spontaneously or under slight pressure. An enanthem characterized by petechiae and small vesicles is almost invariably found over the soft palate if carefully sought.<sup>137</sup> Most patients have cutaneous petechiae in the axillary regions, upper chest, and arms. Lymph nodes become enlarged, particularly in the lateral cervical regions. There are no signs of pulmonary abnormalities. Relative bradycardia and orthostatic hypotension are common. Generally, there is no hepatomegaly or splenomegaly, and jaundice is very rare.

At the end of the first week of evolution, oliguria and different degrees of dehydration occur. Neurologic signs are very common. The patient may be irritable and lethargic, with a fine tremor of the hand and tongue. Moderate ataxia, cutaneous hyperesthesia, and a decrease in deep tendon reflexes and muscular tonicity are present. In females, mild to moderate metrorrhagia is constantly present and, in some cases, is the first sign of the disease.

During the second week of illness, 70% to 80% of the patients begin to improve. In the remaining 20% to 30%, severe hemorrhagic or neurologic manifestations, shock, and superimposed bacterial infections appear between 8 and 12 days after the onset of symptoms. Profuse bleeding may occur in the form of hematemesis, melena, hemoptysis, epistaxis, hematomas, metrorrhagia, or hematuria. The severe neurologic manifestations generally begin with mental confusion, marked ataxia, increased irritability, and intention tremors; these are followed by delirium, generalized convulsions, and coma. Acute renal failure is uncommon, but may occur in terminal cases or after prolonged periods of shock, and is secondary to acute tubular necrosis. Superimposed bacterial infections such as pneumonia and septicemia or thrush can also complicate the clinical course.

Patients begin to improve by the third week of illness and experience a prolonged convalescence. Temporary hair loss is common. Many patients have asthenia, irritability, and memory changes, but these disappear gradually over a period of 1 to 3 months. During convalescence, 10% of Argentine HF patients treated with immune plasma develop a late neurologic syndrome. This late neurologic syndrome appears after a period of 7 to 80 days (mean, 20 days) free of symptoms, differs from the neurologic manifestations of the acute period of Argentine HF, and is characterized by febrile symptoms and cerebellar signs as well as cranial nerve palsies.<sup>138,139</sup>

Clinical laboratory studies are quite helpful in establishing an early clinical diagnosis in South American HF. During the acute phase, there is progressive leukopenia and thrombocytopenia, with counts falling to 1000 to 2000 white blood cells (WBCs) and 50,000 to 100,000 platelets per microliter.

The sedimentation rate is normal or decreased. Almost invariably, there is proteinuria and a urinary sediment containing hyaline-granular casts and red blood cells. Round cells with cytoplasmic inclusions are also found, but are not diagnostic. Serum creatinine and urea are normal or increased in proportion to dehydration and shock in the severely ill patient. In Argentine HF, aspartate transaminase (AST), creatine phosphokinase (CPK), and lactate dehydrogenase (LDH) elevations are common but mild, and hyperbilirubinemia or hyperamylasemia is rare. During the acute illness, cerebrospinal fluid (CSF) is normal, even in patients with severe neurologic disease. However, during the late neurologic syndrome following immune plasma therapy, the CSF may have tens to hundreds of cells with normal sugar and normal or slightly increased protein.

Argentine HF during pregnancy is uncommon, but in the last trimester more than half of patients die, at least in part due to tardy recognition of the disease and failure to administer specific treatment. Congenital malformations, fetal death, and death of neonates has also been seen.<sup>140</sup> Children tend to have a milder clinical course, but severe and even fatal disease has been seen.

### Other South American Hemorrhagic Fevers

Bolivian HF<sup>82,112,141</sup> and Venezuelan HF<sup>83,113</sup> have clinical characteristics similar to those of Argentine HF. Bolivian HF cases from a nosocomial outbreak occurring at high altitude had jaundice and a high mortality, but the reason was not determined.<sup>110</sup> Patients with Venezuelan HF frequently complain of sore throat among their initial symptoms, and hearing loss in convalescence has been reported.

Only a single naturally acquired infection with Sabia virus has been identified, and it resembled other South American HFs except for extensive liver necrosis and jaundice.<sup>142</sup> One laboratory infection appeared to be a mild case of HF,<sup>143</sup> and a second was treated, apparently successfully, with ribavirin and developed only mild disease.<sup>144</sup>

### Lassa Fever

Lassa fever is seen in both sexes and all age groups. Typically, after an incubation period of about 10 days (range, 3 to 21 days), the patient notes the insidious onset of fever, headache, generalized weakness, and malaise.<sup>125,145–150</sup> Within a few days, these may be followed by sore throat with or without visible pharyngitis, cough, retrosternal chest pain, conjunctivitis, abdominal pain, and a variety of other generalized symptoms. The minority of patients with florid Lassa fever may then manifest facial and neck swelling, subconjunctival hemorrhage, and bleeding.<sup>137</sup> The bleeding is typically a mild oozing from the nose, mouth, or genitourinary or gastrointestinal tract and, with the exception of vaginal bleeding in pregnant women, is unlikely to be hemodynamically significant. Maculopapular or petechial rashes have been observed in white-skinned, but not black-skinned patients. Whether this difference reflects ease of observation or different manifestations of Lassa fever based on genetic makeup is uncertain.

Elevated respiratory rates, with or without mild rales on lung auscultation, are frequently noted. Hypotension and tachycardia may be present, especially in more severe cases.

Pleural effusions are common, and pericardial effusions are occasionally seen late in the course of the disease, particularly in males. A variety of encephalopathic and other neurologic manifestations have been noted in severely ill patients, but it is not clear to what extent these represent direct effects of Lassa virus on the CNS, secondary immune-mediated effects, or non-specific metabolic ones common to any critically ill patient.<sup>151,152</sup>

Surviving patients generally begin to defervesce within approximately 10 days of onset. With the exception of sensorineural deafness (see following discussion), recovery is usually complete. Conversely, patients with severe illness may deteriorate rapidly, progressing to shock, delirium, respiratory distress, coma, seizures, and death.<sup>125,149</sup> The contribution of poor fluid balance, nutritional status, and patient monitoring in this setting of limited resources is unknown. Other underlying health problems such as malnutrition, tuberculosis, and acquired immunodeficiency syndrome (AIDS), as well as nosocomial infections, may affect the clinical course of Lassa fever as well.

Lassa fever in pregnant women carries a significantly elevated risk for both the mother and the fetus.<sup>95,153</sup> Maternal mortality is particularly elevated during the third trimester, when fetal death approaches 100%.<sup>153</sup>

Pediatric Lassa fever is less well described but produces a spectrum of disease ranging from undifferentiated febrile illness to severe Lassa fever.<sup>124,154,155</sup> A “swollen baby syndrome” comprised of anasarca, abdominal distention, and bleeding with a high mortality has been described in several Liberian infants.<sup>154</sup> Whether this syndrome is a general feature of Lassa virus infection of infants or related to other concomitant health risks or therapies specific to the area of study is not clear.

Abnormalities in clinical laboratory measurements are usually mild to moderate. Thrombocytopenia, usually not less than 100,000/ $\mu$ L, may be seen. Although often normal, a mild diminution in the WBC count with lymphopenia may occur.<sup>146,149,156</sup> Severely ill patients are more likely to be thrombocytopenic, are usually lymphopenic, and may have an elevated WBC count with neutrophilia. Moderate hemoconcentration and proteinuria are usually present with an elevated blood urea nitrogen (BUN).<sup>146–148,150</sup> These are likely a result of capillary leak, fever, and decreased fluid intake resulting in loss of intravascular volume. The AST is often elevated, and higher values are predictive of a poor prognosis, as is the level of viremia.<sup>157</sup> The disproportionate elevation in AST compared to the alanine transaminase (ALT) value suggests that its source is not solely the liver but rather may result from diffuse ischemic end-organ damage. Disseminated intravascular coagulation (DIC) is not part of the pathogenesis of Lassa fever. A variety of nonspecific electrocardiographic changes have been reported.<sup>158</sup> Based on limited observations, radiographic studies are usually nonspecific and correlate with the physical exam.<sup>159</sup>

Sensorineural deafness is the major chronic sequela of Lassa fever and may occur in up to one-fourth of those infected. Typically, the deafness presents during convalescence. There is no correlation with the severity of the acute febrile illness, level of viremia, or AST. It may be uni- or bilateral and is permanent in approximately two-thirds of cases.<sup>160</sup> Depression and cerebellar ataxia have been reported during recovery, but are relatively uncommon.<sup>152</sup> Lassa virus can often be isolated from CSF; however, a systematic correlation with any of the neurologic manifestations of the disease is not available.<sup>151,160</sup>

Although a broad range of case-fatality rates from Lassa fever have been reported, about 15% is a good estimate in the patient seeking medical treatment. Nigerian outbreaks have often been associated with a higher mortality than those in countries further west in Africa. Community investigations conducted in Sierra Leone found milder infections to be common but the role of preexisting immunity is unresolved.<sup>96</sup> The presence of bleeding, high viremia or antigenemia, and elevated AST independently confer a poor prognosis.<sup>145,149</sup>

### Lymphocytic Choriomeningitis

Typical LCM is characterized by two phases, a period of fever and viremia followed by a CNS phase in which virus no longer circulates, antibodies are found in serum, but virus is still present in the CNS<sup>78,79,116,121–123,161–163</sup> (reviewed in Lehmann-Grube<sup>69</sup> and Peters<sup>164,165</sup>). Neurologic disease is presumed to be immunopathologic and mediated by CD8+ T cells, as is the process seen in the intracranially infected adult mouse.<sup>5,37,166</sup> Immunosuppressed patients inoculated with LCM virus did not develop CNS signs, although virus grew in the brain.<sup>167</sup> A substantial proportion of infections are subclinical, some of the remainder consist of fever alone, and others show both the initial febrile phase and the CNS disease, often with a short afebrile remission between the two.

The disease may begin with abrupt onset of fever, malaise, and myalgia with additional weakness, gastrointestinal symptoms, and occasionally sore throat or cough. Arthralgia, testicular pain, parotid pain, or even frank inflammation may occur. During this phase, which may last from a few days to 2 to 3 weeks, leukopenia, lymphopenia, thrombocytopenia, and elevation of LDH and AST are seen.<sup>78,161,163</sup>

The neurologic phase begins with aseptic meningitis, usually after a short period of defervescence but possibly continuous with the initial febrile stage or even without preceding fever. The findings are those of aseptic meningitis, but headache may be severe and disturbances of consciousness may be seen. Signs of nervous system involvement may last 1 to 4 weeks and virtually always resolve without sequelae. Rarely, LCM may present as encephalitis<sup>122,123</sup> with a very occasional fatal outcome; in the latter case, cerebral neuronal invasion can be demonstrated.<sup>168</sup> The CSF may have normal or low glucose, and cell counts often reach hundreds to thousands of lymphocytes per microliter.

Convalescence may be delayed for several weeks with asthenia, febrile sensations, difficulties in memory, poor cognitive function, headaches, or arthralgia.

Occasionally, LCM virus infection has been associated with ascending paralysis, Parkinson's syndrome, transverse myelitis, or myocarditis, but a causal link remains to be established. Deafness has rarely been reported with LCM<sup>169,170</sup> and may be a feature, based on the similarity to Lassa fever. Rarely, LCM virus has caused a syndrome resembling viral HF.<sup>171</sup>

As in other arenavirus infections, LCM virus can cross the placenta, with fetal infection or death.<sup>78,172,173</sup> The most common manifestation identified has been hydrocephalus with chorioretinitis. This was first reported from Lithuania<sup>174,175</sup> but has been confirmed in Germany,<sup>172</sup> France,<sup>176</sup> and more recently by several cases in the United States.<sup>177–180</sup> This is probably a much more common problem than appreciated.

## Pathology

### Animal Models

Natural and experimental infection of different animals, including guinea pigs, rats, hamsters, and nonhuman primates, have provided useful information on the comparative pathology of arenavirus infections. Lassa virus infection of rhesus monkeys, squirrel monkeys, and guinea pigs demonstrated a wide spectrum of organ tropism involving liver, spleen, lymph nodes, heart, lungs, pancreas, kidneys, and adrenal glands at early stages of infection. The common pathologic findings include hepatocellular necrosis and regeneration, lymphoid necrosis in spleen and lymph nodes, myocarditis, focal arteritis, renal tubular necrosis, and late mononuclear choriomeningoencephalitis.<sup>181–184</sup>

LCM virus infection of marmosets and tamarins can induce a highly fatal disease (callitrichid hepatitis). The histopathologic lesions are similar to those in human Lassa fever and consistently show focal necrosis in the liver, spleen, lymph nodes, adrenal glands, intestine, and pancreas.<sup>185</sup> In addition, LCM virus causes a viral HF syndrome in rhesus monkeys,<sup>31</sup> so it is not surprising that rarely human infection by LCM virus may also produce manifestations resembling HF.<sup>171</sup>

Machupo virus infection of rhesus and African green monkeys causes hemorrhage and necrosis in multiple organs. The hemorrhages are present in the skin, heart, brain, and nasal mucosa; necrosis is observed in the liver, adrenal cortex, myocardium, gastrointestinal mucosa, lymphoid tissue, and epithelial cells of the tongue, mouth, esophagus, and skin. Animals that die late in the course of Machupo virus infection frequently have meningoencephalitis and bronchopneumonia.<sup>186</sup>

Junin virus infection of rhesus monkeys, marmosets, and guinea pigs produces lesions similar to reported human cases of Argentine HF. The common findings include hemorrhage, bone marrow necrosis, mild hepatocellular necrosis, polioencephalomyelitis, and autonomic ganglioneuritis.<sup>187</sup>

Guanarito virus infection of guinea pigs results in focal epithelial cell necrosis of the gastrointestinal tract, interstitial pneumonia, and lymphoid and hematopoietic cell necrosis. Viral antigen is present in lymphoid tissues, macrophages, endothelial cells of multiple organs, pulmonary epithelium, epithelium of the gastrointestinal tract, and other tissues. Intact virions and typical arenavirus inclusions are visualized by immune electron microscopy in these same tissues.<sup>188</sup>

### Human Pathology

Pathologic descriptions of arenavirus infections in humans are limited to a few necropsy series.<sup>182,183,189–191</sup> Gross and microscopic pathologic findings in these human cases are generally similar among different arenavirus infections.<sup>192</sup> Common gross findings at postmortem examinations include ecchymoses and petechial hemorrhages involving skin, conjunctivae, mucous membranes, and internal organs. The degree of hemorrhage varies, and sometimes can be minimal or absent. Conjunctival suffusion, pleural effusion, pericardial effusion, and ascites are frequently present.

Microscopically, congestion and variable degrees of necrosis are usually observed in multiple organ systems. Necrosis is most prominent in the liver (Fig. 66-6) and spleen, but is also

**FIGURE 66-6** Lassa virus infection in the liver, showing multifocal hepatocellular necrosis with cytoplasmic eosinophilia, nuclear pyknosis, cytolysis, and fatty metamorphosis. (Hematoxylin and eosin stain.)

frequently found in adrenal gland, kidney, and gastrointestinal mucosa. The most consistent histopathologic feature is seen in the liver and comprises multifocal hepatocellular necrosis with cytoplasmic eosinophilia, Councilman body formation, nuclear pyknosis, cytolysis, and fatty metamorphosis. Inflammatory cell infiltrates in necrotic areas are usually minimal and, when present, consist of a mixture of mononuclear cells and neutrophils. The spleen usually shows depletion of follicles and focal necrosis. Other pathologic features that may be present in arenavirus infections include mild interstitial pneumonitis, diffuse alveolar damage, myocardial necrosis, and acute renal tubular necrosis.

Because none of these pathologic features are specific, a confirmatory assay such as immunohistochemistry or *in situ* hybridization is essential to establish a definitive tissue diagnosis, and such assays can also delineate the spectrum of tissue tropism as well as elucidate possible pathogenic mechanisms.

In Lassa fever, the localization of viral antigens can be summarized as: (1) hepatocytes, especially those in the areas

**FIGURE 66-7** Antigens of Lassa virus are present in hepatocytes and sinusoidal lining cells, including Kupffer cells and endothelial cells. (Immunoalkaline phosphatase staining, Naphthol fast red substrate with light hematoxylin counterstain.)

of necrosis (Fig. 66-7); (2) cells of the mononuclear phagocytic system such as Kupffer cells in hepatic sinusoids, alveolar macrophages, and endothelial cells; (3) mesothelial cells lining the pericardium, pleura, peritoneum, and serosal surfaces of other organs; and (4) specialized cells involved in hormone secretion, including those in the adrenal gland, ovary, uterus, placenta, and breast.<sup>184</sup>

In Argentine HF, ultrastructural and immunohistochemical studies reveal characteristic intracellular viral inclusions that are more prominent in lymphoid tissues, coincident with the presence of Junin virus antigens. Macrophages are usually the cell type involved, although there is often necrosis in adjacent lymphocytes.<sup>193</sup> In the kidney, a large number of virus-like intracytoplasmic particles are found in distal and collecting tubules coincident with severe tissue necrosis and large quantities of Junin virus antigen as demonstrated by immunofluorescence.<sup>194</sup> Morphologic studies of the bone marrow indicate that an acute and transient arrest of hemopoiesis occurs, with bone marrow hypocellularity, but without permanent hematologic sequelae in survivors.<sup>195</sup>

Although further study is needed, some possible pathogenetic mechanisms in arenavirus infections can be suggested from these findings.

1. The presence of abundant Lassa virus antigens in or adjacent to the necrotic hepatocytes and Junin virus particles near necrotic foci in the kidney suggests that cellular necrosis can be a consequence of direct viral infection. Although hepatocellular necrosis is the most consistent histopathologic feature in arenavirus infections, it alone is insufficient to explain the fatal outcome in most instances.
2. Lymphoid tissues are the main sites of viral replication, as evidenced by the large amount of viral antigen present, high virus titers when determined, and the presence of lymphocytopenia and lymphocyte depletion in spleen and lymph nodes.
3. The widespread hemorrhages in arenavirus infections do not appear to be a result of DIC or clotting factor abnormalities; instead, the interactions of viral antigens with platelets, inflammatory cells, macrophages, and endothelial cells may play a more critical role in pathogenesis. The demonstrated infection of macrophages and endothelial cells may induce secretion of physiologically active substances, including cytokines and other inflammatory mediators, and subsequently cause microvascular instability leading to capillary leak syndrome.
4. The involvement of mesothelial cells can explain serous effusions commonly seen in patients with arenavirus infections.
5. The presence of viral antigens in hormone-secreting cells suggests that an interaction between arenaviruses and hormone receptors may exist. This interaction may further enhance the pathogenicity of the virus and cause more severe pathophysiologic effects. These effects might contribute to the higher mortality of pregnant women with Lassa fever and Argentine HF.

## **PATHOGENESIS AND IMMUNITY**

The paucity of histologic lesions to explain disordered organ function and death is a common characteristic of all

arenavirus infections, particularly arenaviral HF. Studies of LCM virus have shown that the infected cell may have altered function without morphologic changes, but this has not been examined in the HF. In South American HF, the altered pathophysiology seems to be the result of direct viral action in contrast to the more well-known and well-studied mouse models of LCM virus infection in which immunopathologic T-cell action causes acute encephalitis, and B-cell products result in chronic immune complex disease.<sup>37,39</sup> Several studies failed to demonstrate immune complexes, complement activation, or DIC as relevant pathogenic mechanisms in Argentine HF.<sup>196,197</sup> Immunosuppression of the Junin virus-infected guinea pig or the hamster undergoing systemic LCM virus infection failed to ameliorate disease.<sup>198,199</sup> Mediators released or activated as a result of the virus-cell interactions, such as lymphokines, vasoactive mediators, and proteolytic enzymes, may also explain some of the alterations.

In Argentine HF, bleeding itself seems to be a joint outcome of thrombocytopenia, abnormal platelet function induced by a plasma component,<sup>200</sup> and alterations in blood coagulation with activation of fibrinolysis. Hemostatic abnormalities include prolongation of activated partial thromboplastin time (APTT); low levels of factors VIII and IX; increased values of factor V, von Willebrand factor, and fibrinogen; and mild decreases in antithrombin III as well as plasminogen. Endothelial cell involvement is also suspected considering that Junin virus replicates well in cultured endothelial cells, a feature supported in human disease by increased levels of von Willebrand factor.<sup>197,201</sup>

Argentine HF is also characterized by an acute transitory immunodeficiency. There is a lag in the humoral immune response, with antibodies appearing during the second week of illness, coincident with the recovery of the patients.<sup>196</sup> During the acute phase, cell-mediated immunity is also depressed as measured by delayed-type hypersensitivity to nonviral recall antigens and lymphocyte proliferation stimulated by mitogens, as well as marked changes in the T-cell subpopulations; all return to normal values in early convalescence.<sup>202,203</sup> Both cellular immunity and antibody are important in recovery by Junin virus-infected guinea pigs<sup>204</sup> and in protection of vaccinees.<sup>205,206</sup>

Very high titers of endogenous interferon (IFN) have been demonstrated in serum samples of Argentine HF patients during the acute period of the disease and are significantly higher in fatal cases.<sup>207</sup> The levels of IFN- $\alpha$  decreased after the transfusion of immune plasma. Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) levels are also markedly elevated, particularly in fatal cases.<sup>208</sup> Another study suggested an association between histocompatibility antigens and the severity of Argentine HF.<sup>209</sup> Lassa fever probably has a similar pathogenesis as South American HF. Major differences are the less severe thrombocytopenia, the minor neurologic involvement, and the mechanism of recovery from acute disease. Although platelet counts do not fall to the low levels found in South American HF, there are soluble serum factors that mediate a profound but reversible inhibition of platelet aggregation,<sup>200</sup> and extensive inhibition is associated with clinical bleeding. Signs of neurologic disease are less frequent in Lassa fever, but may have been underestimated; indeed, Lassa virus has been isolated from CSF on several occasions, in contrast to Argentine HF in which virus has never been isolated from CSF or CNS tissues in spite of the frequent appearance of brain dysfunction.

Cytokine activation is also present in Lassa fever.<sup>210</sup> In humans and in animal models, recovery from Lassa fever is not mediated by antibody, as judged by the low, late, and variable levels of in vitro neutralization by convalescent serum and the lack of protection in passive transfer experiments.<sup>31,211</sup> Spleen cell transfers in strain 13 guinea pigs suggest that cellular immunity is responsible for clearing viremia and survival.

The role of cellular immunity in recovery may also be relevant to the severity of Lassa fever in pregnant women. The placenta does not express maternal major histocompatibility complex (MHC) antigens,<sup>212</sup> but in Lassa fever it is highly infected (W-J Shieh, unpublished data); by analogy with the situation that holds for LCM virus-infected neurons, which do not express class I major histocompatibility complex (MHC) and cannot be lysed by host CD8+ T lymphocytes,<sup>213</sup> it seems likely that maternal T cells cannot control placental infection.

The Pichinde guinea pig model has been explored in detail as a model of severe arenavirus infection, and results suggest that many of the same mediators activated in septic shock are involved in the pathogenesis of Lassa fever.<sup>31,214</sup> Sulfidopeptide leukotrienes, catecholamines, platelet activating factor, endorphins, and TNF- $\alpha$ <sup>215-217</sup> are all activated. Excessive sodium loss occurs in the face of extensive infection of the mineralocorticoid-secreting zones of the adrenal cortex, although serum corticosteroid levels are somewhat elevated. One potentially important finding is the decrease in cardiac index and increase in peripheral vascular resistance seen from the outset, and the poor response to fluid infusion. This resembles the situation in hantavirus diseases but contrasts with the usual situation in septic shock. These results, combined with the pulmonary infection and interstitial infiltrates seen in humans and animal models, recommend that fluids be used with caution in supporting the circulation.

Although little is known about the pathogenesis of sensorineural deafness, its occurrence during convalescence, as well as lack of association with severity of the acute febrile illness, peak AST level, or antiviral therapy, suggests a possible immune-mediated injury.<sup>213</sup> Auditory patterns resemble idiopathic nerve deafness.<sup>218</sup>

## DIAGNOSIS

### Differential Diagnosis

During the first week of illness, the clinical manifestations of South American HF are nonspecific and can be confused with several acute febrile conditions. Among the infectious diseases, the differential diagnosis includes typhoid fever, hepatitis, infectious mononucleosis, leptospirosis, hantavirus pulmonary syndrome, dengue, dengue HF, and rickettsioses. Malaria should also be considered in endemic areas. Diseases presenting with hematologic or neurologic alterations such as intoxications, rheumatic diseases, and blood dyscrasias may also be mistaken. In the respective endemic areas or in patients with a history of travel to the specific geographic regions, a febrile syndrome with leukopenia and thrombocytopenia is suspicious of one of the South American HF.

As with the South American diseases, the initial presentation of Lassa fever is often very nonspecific, and the differential diagnosis includes most febrile illnesses found in West Africa (see Chapter 65). Malaria, typhoid, and bacillary dysentery are important conditions to rule out or treat empirically.

Combinations of clinical variables have been examined to facilitate determination of both clinical diagnosis and outcome of patients with Lassa virus infection.<sup>149</sup> Although statistically significant positive predictive values can be obtained, they apply only to areas of high prevalence (41% of all adult febrile hospital admissions in this example), a condition unlikely to be met except in selected epidemic settings or in relatively uncommon areas of intense endemic transmission. The pharyngitis often seen in Lassa fever can be a confusing feature.

LCM virus infection should be suspected in any acute febrile disease associated with myalgia, thrombocytopenia, and leukopenia. Orchitis may occur, and CNS manifestations sometimes develop later. The classic presentation of LCM virus infection is aseptic meningitis occurring in the fall, particularly if an initial prodromal period of fever, perhaps with a remission, occurs before the CNS phase. High lymphocyte counts and low glucose values may be found in the CSF, leading to confusion with granulomatous meningitis. History of mouse or hamster contact may also be elicited but is often not present. If TORCH (*toxoplasma*, *rubella*, *cytomegalovirus*, and *herpesvirus*) testing is negative or doubtful in cases of neonatal hydrocephalus or chorioretinitis, LCM virus testing should be done.

## Laboratory Diagnosis

In the arenaviral HF, viremia occurs throughout the acute febrile period, and the viruses can readily be isolated from blood and from lymphoid tissues of fatal cases.<sup>219</sup> Isolation is usually performed in Vero cells. The presence of virus can also be detected by ELISA for viral antigen or reverse transcription–polymerase chain reaction (RT-PCR). Fatal cases can also be diagnosed by immunohistochemistry on fixed tissues. Antibodies are usually measured by IFA<sup>52</sup> or increasingly by ELISA. Neutralization tests are extremely valuable for confirming specificity of reactions provided the arenavirus species is sensitively neutralized by convalescent serum.<sup>31</sup>

In Argentine HF, cocultivation of peripheral blood mononuclear cells improves the sensitivity of virus recovery.<sup>220</sup> Viral isolations can also be performed in guinea pigs or suckling mice. The ELISA is the method of choice for serologic diagnosis. RT-PCR has been successfully applied and can play a role in establishing etiologic diagnosis in patients dying before the appearance of the specific antibodies.

Recent Bolivian HF cases<sup>111</sup> have been diagnosed by antigen detection ELISA and immunoglobulin M (IgM) ELISA, although the classic approach employs suckling hamster inoculation for virus isolation and IFA with confirmatory neutralization tests for serology.<sup>52</sup>

In Africa, acute Lassa fever is best diagnosed by the combined ELISA for Lassa IgM antibody and antigen, which yields a sensitivity over 90% within 48 hours of admission.<sup>221,222</sup> Sensitive RT-PCR assays exist, but even in developed countries strain variation and problems of cross-contamination pose practical problems.<sup>223,224</sup> Lassa antigen is usually present in blood within a few days of infection and becomes undetectable after the appearance of IgM ELISA antibody, which typically appears a few days after the onset of illness and peaks by about 10 to 12 days. IgG ELISA antibodies typically take longer to develop, but are present in almost all patients

by approximately 3 weeks and last for a period of years. It is unclear whether reinfection takes place, although its occurrence is suggested by the finding of significant sharp IgG IFA titer elevations in individuals previously shown positive, sometimes in association with mild febrile disease.<sup>149</sup> Lassa virus can be isolated from serum early in the disease course in about two-thirds of surviving and virtually all fatal cases. In survivors, this viremia is typically cleared by about 2 weeks. Conversely, in fatal cases, viremia persists unabated until death. Virus has also been isolated from serous effusions and a wide array of body tissues.<sup>147,157,183</sup>

Other serologic tests may be applied to Lassa fever, including IFA, which, like the IgM ELISA, may detect antibodies while patients are still acutely ill.<sup>157</sup> In contrast, neutralizing antibodies appear late in Lassa fever, often several weeks after disease resolves.<sup>211</sup> Furthermore, the final response is low in titer, best seen with a constant serum-varying virus test, and intensely complement dependent. It has been clearly shown in monkeys and guinea pigs that this neutralizing titer correlates with the ability to transfer protection (reviewed in Peters and associates).<sup>31</sup>

LCM virus circulates in the blood before the onset of CNS symptoms and later can be isolated from CSF by inoculation of adult mice intracranially or by use of Vero cells.<sup>13,69,225</sup> After the onset of CNS disease, ELISA IgM capture antibody tests in serum and CSF should be positive<sup>226</sup> (also T.G. Ksiazek, unpublished observations). The LCM virus antibody response resembles that to Lassa virus in that the neutralizing antibody response is greatly delayed, complement dependent, and of poor quality.<sup>222,227</sup> An RT-PCR procedure with sufficient sensitivity to detect LCM virus in clinical samples has been described, simplifying future viral diagnosis.<sup>228</sup>

## TREATMENT

### General Supportive Treatment

Supportive treatment consists of adequate hydration, symptomatic measures, and proper management of the neurologic alterations, blood losses, shock, and superimposed infections. There is no indication for the use of steroids or alpha interferon. Medication should be given by the oral or intravenous route. Intramuscular and subcutaneous injections are contraindicated because of the risk of hematomas.

In the Argentine HF–endemic area, several observations have been made: Pneumonia is the most common secondary bacterial infection and is often accompanied by radiographic changes and an increase in fever but not by leukocytosis; it usually responds to antibiotics. Platelet transfusions have been used, but the complex nature of the coagulopathy and clinical experience suggest they are not useful. Strategies such as desmopressin or activated factor VII have not been evaluated. Transfusions are needed occasionally, but most of the severe forms are neurologic. It is useful to sedate agitated patients with diphenhydramine or diazepam; diazepam also gives some protection against seizures. Cerebral edema may require both steroids and mannitol.

### Virus-Specific Therapy

For Argentine HF, a specific treatment is available: the transfusion of immune plasma within the first 8 days of onset

of symptoms.<sup>138,203</sup> This treatment reduces the case-fatality rate, from 15%–30% to less than 1%, and is now standardized based on the amount of neutralizing antibodies to Junin virus infused. Immune plasma is of no benefit to patients when it is initiated after 8 days of illness.

For the other South American HF, the specific treatment suggested is ultravenous ribavirin, which should be considered for off-label use unless a proven alternative effective therapy is available.<sup>144,229</sup> Ribavirin may also prove useful in the treatment of Argentine HF patients<sup>203</sup>; this may be increasingly important as human immunodeficiency virus (HIV) and hepatitis C infections increase in the pampas, making donor selection more difficult, and because plasma-treated patients develop lower titers in convalescence, requiring more plasma for effective therapy of subsequent patients.<sup>203</sup>

Lassa fever can be treated effectively with the nucleoside analogue ribavirin. The drug was found to be highly effective in vitro and in a monkey model, leading to trials in West Africa that established its utility in human Lassa fever.<sup>230,231</sup> Patients with poor prognostic indicators (e.g., AST >150 units/mL) should be treated with intravenous ribavirin given in a dose of 30 mg/kg initially, 15 mg/kg every 6 hours for 4 days, and 7.5 mg/kg every 8 hours for 6 more days (this is not a licensed drug). The drug should be diluted in 150 mL of 0.9% saline and slowly infused<sup>232</sup> over a 30-minute period. Modest anemia should be expected, both from hemolysis and from a fully reversible normoblastic maturation arrest.

Uterine evacuation appears to improve survival significantly in pregnant women with Lassa fever.<sup>153</sup> Although contraindicated in pregnancy, the elevated maternal mortality rate, along with the almost universal fetal loss, suggests that ribavirin could be used as well, especially in the third trimester when maternal mortality is particularly high.

Neutralizing antibodies have been effective in laboratory models of Lassa fever, but this therapy should not be used unless the infused material is standardized by laboratory assays. Only supportive management is available for LCM.

## PREVENTION

### Containment of Patients

Acutely ill patients with South American HF or with Lassa fever are viremic during the acute phase of their illness, and the viruses are infectious by parenteral inoculation. Needle precautions should be emphasized, and transmission of Lassa fever within hospitals by inadequate parenteral precautions has caused serious epidemics in African hospitals.<sup>130</sup> Person-to-person transmission of Lassa fever is uncommon in the medical care setting,<sup>128</sup> but has occurred in the hospital as well as in the community so that barrier nursing precautions should be strictly enforced. Airborne transmission of Lassa fever has not been suspected to be a problem except in a single hospital epidemic in Nigeria.<sup>129</sup>

The South American HF have not been regarded as highly contagious in the endemic areas where they occur, and person-to-person transmission is uncommon. Nevertheless, there are unusual patients who have disseminated both Junin (J.I. Maiztegui, unpublished observations) and Machupo viruses<sup>110–112</sup> to hospital staff and to families, in some

instances suggesting aerosol transmission. Although the major focus should be on the proper patient care using basic precautions that will prevent parenteral and droplet exposure to blood and body fluids, the authors believe that, when possible, it is prudent to implement small-particle aerosol precautions once patients with arenavirus HF are identified.<sup>144,233–236</sup>

Clinically well patients leaving the hospital are not generally contagious. HF patients have transmitted virus to spouses in convalescence so that intimate contact should be cautious and condoms should be used during sex for 2 to 3 months. Lassa virus has been isolated from urine for several weeks, and the use of disinfectant in the toilet bowl before voiding is advised. Breastfeeding is thought to be a risk factor for transmission from mother to infant and should be temporarily avoided unless there is no other way to support the baby.

It is not known if arenaviruses could adapt to rodents outside the endemic area. The striking rodent species-specificity of arenaviruses seen to date would argue that this is unlikely, but the ability of LCM virus to maintain itself within hamster colonies<sup>13</sup> and of Lassa virus to chronically infect newborn laboratory mice<sup>164</sup> suggests that precautions should be taken to minimize the discharge of exotic arenaviruses to the environment. For these reasons, we also recommend the sterilization of all materials leaving a patient's room in nonendemic areas, including adding disinfectant to toilets before use.

Barrier nursing in African hospitals should be emphasized, both because of the possibility of transmission and the potential presence of other viral HF. Locally applicable methods for such activities have been developed.<sup>237</sup>

### Rodent Control

Rodent control has been successful in the control of Bolivian HF epidemics occurring in towns of the Beni Department,<sup>238</sup> but sporadic cases still occur after rural exposure or contact with a case.<sup>111</sup> For Argentine HF, rodent control or the control of human contact with infected rodent populations is impractical.

The fecundity and ubiquity of the *Mastomys* species complex across West Africa make widespread elimination of rodents unfeasible as a control measure for Lassa fever. Intense trapping in towns may be indicated during epidemics, although care should be taken to ensure that disposal of the trapped rodent does not inadvertently lead to exposure to potentially Lassa virus–infected blood, urine, or feces. Educational campaigns to appropriately store foodstuffs and avoid rodents as a food source, a practice common in some areas of West Africa, may have some impact.

LCM prevention depends on the exclusion of wild mice from dwellings, workplaces, and areas where colonized rodents are housed. The last is particularly important because of the risk of dissemination of infected animals to the pet trade or to laboratories. The occult infection of mouse colonies has been a recurring theme ever since LCM virus was first recognized.<sup>13,239,240</sup> In addition, the virus can be maintained in colonies of hamsters and possibly other rodents, and pet rodents could be infected if wild mice gain access. Pregnant women, in particular, must be protected from infection because of the risk of fetal damage.<sup>180</sup>

## Vaccination

A live attenuated Junin virus vaccine (Candid #1)<sup>86</sup> with proven safety, immunogenicity, and efficacy in preventing Argentine HF is now available for use in high-risk populations.<sup>206</sup> Application of 175,000 doses targeted to the maximum risk groups has resulted in a major reduction in morbidity and mortality from Argentine HF (see Fig. 66-5). With sufficient supplies of vaccine to protect the whole population at risk, Argentine HF would be definitively controlled. Candid #1 may also be effective in the prevention of Bolivian HF, as suggested by preclinical studies, but the vaccine does not cross-protect against infection with Guanarito or Sabia viruses in experimental studies (P. B. Jahrling, personal communication, 1995).

Definitive control of Lassa fever in Africa urgently requires an effective vaccine. Immunization with the vaccinia-vectored GP gene of Lassa virus has spared nonhuman primates from death and given partial protection from disease and viremia, suggesting the feasibility of a Lassa vaccine.<sup>241</sup> Other approaches have also protected laboratory animals, but the use of killed vaccines has not generally been successful in preventing arenavirus disease (reviewed in Clegg and Sanchez).<sup>242</sup>

# Bunyaviral Fevers: Rift Valley Fever and Crimean-Congo Hemorrhagic Fever

DOUGLAS M. WATTS  
RAMON FLICK  
C.J. PETERS  
ROBERT E. SHOPE

## AGENTS

Viruses of the family Bunyaviridae are classified into five genera: *Orthobunyavirus*, *Phlebovirus*, *Hantavirus*, *Nairovirus*, and *Tospovirus*. Member viruses of these genera contain negative sense, trisegmented, single-stranded RNA. The viruses replicate in the cytoplasm and mature in association with the Golgi apparatus. The virions are spherical, approximately 90 nm in diameter with a lipid envelope into which are inserted spike-like structures containing two surface glycoproteins responsible for attachment and induction of neutralizing antibody. Each RNA segment consists of one or more genes: the small (S) segment codes for the nucleocapsid protein; the middle-sized (M) segment for the glycoprotein precursor, which is posttranslationally cleaved into the two mature glycoproteins; and the large (L) segment for the polymerase. The S and M segments of some viruses encode additional nonstructural proteins (NS<sub>S</sub> and NS<sub>M</sub>, respectively).<sup>1</sup>

Bunyaviral fevers are commonly encountered in the tropics, but the cause is usually undiagnosed because laboratory diagnostic capabilities are lacking. The clinician by default may treat the patient for malaria or another commonly suspected febrile illness. The family Bunyaviridae contains at least 41 tropical viruses that cause fever and sometimes rash.<sup>2</sup> A few of these viruses also cause meningoencephalitis, hemorrhage, arthritis, or retinitis. Two important bunyavirus infections found in tropical Africa and elsewhere are associated with hemorrhage and are sometimes fatal; these are Rift Valley fever, caused by a *Phlebovirus*, and Crimean-Congo hemorrhagic fever, caused by a *Nairovirus*.

## EPIDEMIOLOGY

### Rift Valley Fever

Rift Valley fever (RVF) virus is a mosquito-borne agent serologically related to the sandfly fever viruses.<sup>3</sup> The virus

infects domestic ruminants, primarily sheep, cattle, and goats, and on occasion causes explosive and devastating outbreaks among these animals and humans. RVF virus was first isolated in 1930 during an outbreak of hepatitis and abortion in sheep in the Rift Valley of Kenya.<sup>4</sup> The disease was for many years thought to be localized in the Rift Valley of Africa, where it regularly appears in sheep and cattle during periods of heavy rain, but the virus has now been demonstrated to be enzootic in most countries of sub-Saharan Africa. In 1977, RVF virus was transported out of the tropics north to Egypt, where it caused a "virgin soil" epidemic in an estimated 200,000 people, with 598 reported deaths in the Nile delta.<sup>5</sup> In 1987, an epidemic involving about 1200 persons in Mauritania was linked to the opening of the Diama Dam near the mouth of the Senegal River.<sup>6</sup> RVF was again detected in Mauritania in 1998, and in Egypt during 1993 and 1997, after an absence of 13 years.<sup>7-9</sup> In 2000, an outbreak of RVF occurred on the Red Sea Coast of Saudi Arabia and Yemen and represented the first documented cases outside of Africa and Madagascar.<sup>10</sup> Irrigation farming and accumulation of water in depressions that supported large numbers of mosquitoes were correlated with many of the human cases in the Arabian Peninsula. Continued surveillance is required to determine whether an enzootic cycle of RVF virus is established in Egypt and on the Arabian Peninsula.

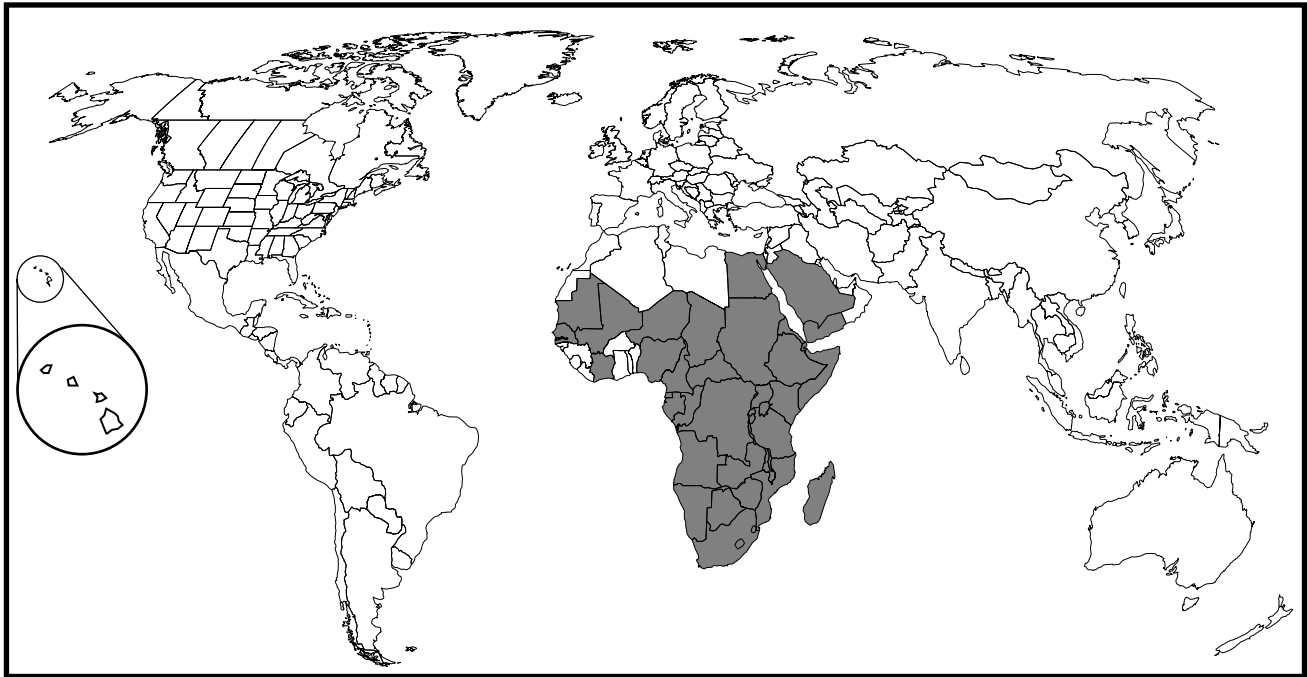

Several species of *Culex* and *Aedes* mosquitoes have been implicated as vectors during epizootics and epidemics of RVF. The enzootic maintenance and transmission cycle is not fully understood; however, studies in Kenya showed that RVF virus was maintained over dry seasons in the eggs of flood-water *Aedes* mosquitoes.<sup>11</sup> The infected eggs remain dormant in the dambos (depressions) of East Africa. After heavy rains, the eggs hatch and are believed to give rise to a new batch of infected mosquitoes that initiate mosquito-livestock-mosquito cycles involving several different species as vectors. RVF transmission also results from direct and aerosol exposure to blood and amniotic fluids of infected sheep and cattle as an occupational disease in butchers, veterinarians, and farmers. Person-to-person transmission has not been reported.

### Crimean-Congo Hemorrhagic Fever

Crimean-Congo hemorrhagic fever (CCHF) virus is a tick-borne agent that was first definitively recognized in the Crimea at the end of World War II when Soviet troops returned to assist in cultivation of tick-infested land left fallow during the war.<sup>12,13</sup> The agent was named Crimean hemorrhagic fever virus and was subsequently found to be indistinguishable from a virus isolated in 1956 from a febrile child in Stanleyville (now Kisangani), Democratic Republic of the Congo, leading to the current designation of CCHF virus.<sup>14</sup> Since the discovery of this disease, the virus or serologic evidence of infection has been found in tropical Africa and temperate Europe and Asia as far east as western China.<sup>15,16</sup>

CCHF virus is serologically related to two other nairoviruses—Dugbe and Nairobi sheep disease viruses—that cause febrile disease in humans.<sup>17</sup> CCHF virus distribution coincides with that of its primary vector, *Hyalomma* ticks. These ticks in the immature stages feed on rodents and ground birds, and in the adult stage on cattle and other large mammals.<sup>15</sup> The wild vertebrate and domestic animal

Rift Valley Fever Virus and Antibody

hosts do not become sick. Humans contract CCHF through the bite of an infected tick, squashing an infected tick, aerosols, or contact with blood or tissue from infected animals, or via the nosocomial route. Outbreaks are usually small, fewer than 100 cases, and more commonly involve

agricultural workers, especially abattoir workers; military personnel or campers; and medical care workers.<sup>15,16,18–20</sup> Nosocomial spread among hospital staff is common, and strict universal precautions should be taken with hospitalized cases of CCHF.<sup>21</sup>

Crimean-Congo Hemorrhagic Fever Virus and Antibody

## DISEASES

### Rift Valley Fever

Human infections with RVF are usually associated with a brief, self-limited febrile illness.<sup>3,22</sup> The incubation period is typically 2 to 6 days. Most patients have a sudden onset of fever, malaise, severe myalgia with lower backache, chills, headache, retro-orbital pain, photophobia, and anorexia. Fever usually lasts for 4 days. In a minority of patients, fever returns after 2 or 3 days, accompanied by return of symptoms, flushed face, nausea, vomiting, and injected conjunctivae. Most persons infected with RVF virus recover without sequelae, although convalescence may take 2 or 3 weeks.

In about 1% of cases, RVFV infection is associated with two severe complications.<sup>3,5-7,22-24</sup> *Hemorrhagic fever* is manifested as epistaxis, hematemesis, melena, and ecchymoses at sites of inoculations. Onset is usually early in the course of illness, and the syndrome carries a poor prognosis. The illness progresses to disseminated intravascular coagulation (DIC), anemia, leukopenia, thrombocytopenia, renal impairment or failure, and hepatitis as evidenced by abnormal liver transaminases, prolonged prothrombin time (PT) and partial thromboplastin time (PTT), and fibrin degradation products. Jaundice is manifested early in the course. Death follows massive gastrointestinal hemorrhage, oliguria, or anuria, associated with fibrin deposition in glomeruli and damage to proximal tubules. Myocardial necrosis occurs in some fatal cases. Death occurs within 3 to 6 days; survivors recover slowly. *Encephalitis* may develop a week or more after the febrile phase as severe headache, meningismus, confusion, and vertigo with cerebrospinal fluid (CSF) pleocytosis. The patient's condition may deteriorate with stupor or coma, and survivors may have residual brain damage.<sup>7</sup>

In 1% to 10% of survivors, retinopathy presents about 7 to 20 days after the primary fever. The patient has decreased visual acuity in one or both eyes. Retinitis with macular cotton wool exudates and edema appears in one or both eyes. Lesions may resolve, but severe defects become permanent with loss of central vision.

### Crimean-Congo Hemorrhagic Fever

The incubation period of CCHF is 3 to 6 days in nosocomial outbreaks and 2 to 12 days in other situations.<sup>15,25</sup> Outbreaks of CCHF are focal in nature. The clinical spectrum ranges from fever, malaise, and prostration to severe and fatal hemorrhagic disease. The case fatality rate has varied from 10% to more than 50%, with most deaths occurring 5 to 14 days after onset. Illness begins with sudden onset of symptoms, including dizziness, neck pain and stiffness, myalgia, especially in the lower back, headache, eye pain and photophobia, arthralgias, chills, anorexia, sore throat, nausea and vomiting, and abdominal pain. Patients may develop altered consciousness progressing to aggressive behavior and unconsciousness. The face is flushed, as are the neck and upper chest. Conjunctival injection and congestion of the pharynx and soft palate are also observed. About 50% of patients develop hepatomegaly. In moderately severe illness, fever lasts 5 to 20 days (average 9 days). The illness may be biphasic with fever followed by one to two afebrile days, then return of fever associated with epistaxis, petechiae, purpura, and thrombocytopenia. Some patients develop jaundice.

Hemorrhage often begins with blood leakage at sites of needlesticks, and may become profuse. Shock ensues in severe cases and may be accompanied by liver failure, cerebral hemorrhage, anemia, dehydration, diarrhea, myocardial infarction, pulmonary edema, DIC, and pleural effusions. Defervescence occurs between days 7 and 20 with cessation of bleeding and general improvement. Convalescence is prolonged, usually 2 to 4 months, and is characterized by weakness, confusion, asthenia, alopecia, and neuralgias.

## PATHOGENESIS AND IMMUNITY

### Rift Valley Fever

RVFV infections, like those of other phleboviruses, are regulated primarily by interferon and neutralizing antibodies, with cellular immunity occupying a much lesser role.<sup>26</sup> Reconstructing the human disease based on available information and animal models, we suppose that mosquito or aerosol infections lead to a viremic phase. An early interferon response protects endothelium and hepatocyte targets.<sup>27</sup> If extensive target cell infection occurs, the acutely cytolytic RVFV infection results in extensive hepatitis and also initiates DIC, a lethal combination that may be tilted toward either pathogenic mechanism.<sup>23</sup> The extensive DIC can result in renal failure in the monkey model.<sup>28,29</sup> In rodents, the host genotype is an important determinant of the type of disease resulting from infection.<sup>30</sup> The encephalitis observed in a minority of humans appears to be a consequence of a lytic viral process.<sup>31</sup> In rodent models, there is a multifocal, acutely necrotic process,<sup>30,32</sup> which also is seen in intracranially inoculated nonhuman primates.<sup>33</sup> The pathogenesis of the retinal disease is not well understood, although some data suggest that it is a consequence of a retinal vasculitis.<sup>34</sup>

Viremia and either hemorrhagic fever or uncomplicated disease from RVFV end with the appearance of the neutralizing antibody response.<sup>26,27</sup> The critical phases of disease occur before host cellular effector mechanisms come into play. In the case of late encephalitis, histologic study shows an acute suppurative lesion that does not have the lymphocytic infiltrates characteristic of T cell-mediated immunopathologic disease. The protective mechanisms of vaccines are thought to be based almost entirely on a neutralizing antibody response.<sup>26,35</sup>

### Crimean-Congo Hemorrhagic Fever

Clinicopathologic studies indicate that all patients present with abnormal clinical laboratory test results, but the changes are moderate in nonfatal infections and marked in patients with fatal outcomes.<sup>36-38</sup> The course of infection is characterized by a transient leukopenia. Creatine kinase (CK) levels are increased early during the first week of disease, and then decline and subsequently increase markedly in fatal cases. The elevated CK coincides with elevated blood urea levels. In addition, serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels increase during the latter half of the first week. The elevated levels of CK, AST, and ALT are accompanied by an increase in alkaline phosphatase,  $\gamma$ -glutamyltransferase, and lactate dehydrogenase. Patients have proteinuria during the first week of illness, and the total

serum protein and albumin levels are decreased during the first and second week in severely ill patients, despite corrective therapy.

Thrombocytopenia is a prominent feature of CCHF viral infection. Platelet counts are extremely low during the early phase of illness among fatal cases, and decrease to thrombocytopenic levels for all patients by the end of the first week of illness. The more prominent findings for CCHF patients are the grossly abnormal prothrombin ratio (PR), activated partial prothrombin time (APPT), thrombin time (TT), fibrinogen, and fibrin degradation products values recorded during the course of fatal infections. Most patients show a decline in hemoglobin during the second week of illness, even patients who do not have hemorrhagic manifestations. In summary, the occurrence during the first 5 days of illness of leukocyte counts  $\geq 10 \times 10^9/L$ , platelet counts  $\leq 20 \times 10^9/L$ , AST  $\geq 200$  U/L, ALT  $\geq 150$  U/L, PTT  $\geq 60$  seconds or fibrinogen  $\leq 110$  mg/dL are  $\geq 90\%$  predictive of fatal outcomes.

Knowledge of the pathogenesis of CCHF is based primarily on descriptions of autopsied tissue and therefore limited to changes that occur in the terminal stages of disease.<sup>37,39</sup> Immunohistochemical and in situ hybridization studies on formalin-fixed human tissues indicate that the main targets of CCHF viral infection are mononuclear phagocytes, endothelial cells, and hepatocytes, accompanied by parenchymal necrosis in the liver. Viral antigen and viral RNA were present within cells lining hepatic sinusoids, including Kupffer and endothelial cells, as well as in endothelial cells of other tissues and lymphoreticular cells of the spleen. The presence of virus in the mononuclear phagocytes and endothelial cells is believed to reflect phagocytic and immunologic activities related to virus clearance, or these cells may support the replication and shedding of virus back into circulation. While evidence of necrosis is not readily demonstrated in the mononuclear phagocytes and endothelial cells, necrosis and depletion of lymphoid cells are prominent in splenic tissue. The absence of necrosis in infected mononuclear phagocytes and the depletion of lymphoid cells may protect the virus from phagocytosis and suppress the immune response, thereby allowing the virus to replicate and spread in CCHF patients. In addition, infection of mononuclear phagocytes and endothelial cells could play a role in the pathogenesis of CCHF by causing secretion of cytokines and other inflammatory mediators.

Viremia and uncomplicated disease associated with CCHF viral infection end with the onset of the neutralizing antibody response. In nonfatal CCHF cases, IgM and IgG antibody can be demonstrated as early as day 7 to 9 after the onset of illness. In contrast, an antibody response is usually not demonstrable among fatal cases, suggesting that the humoral immune response is important for recovery.

## DIAGNOSIS

Several classical and molecular techniques can be used to diagnose CCHF<sup>15,16,37-42</sup> and RVF<sup>24,42-45</sup> viral infections. The viruses are easily isolated by intracerebral inoculation of blood or organs in baby mice or by inoculation of Vero cell culture (Fig. 67-1). Other vertebrate cell cultures are also susceptible. Mice sicken and the virus is identified in brain or liver by immunofluorescence or by reverse transcription-polymerase

**FIGURE 67-1** Electron micrograph of Rift Valley fever virus grown in BHK-21 cells, showing virus particles (arrows) maturing within the Golgi apparatus and cytoplasmic vesicles. Bar = 100 nm. (Courtesy of Dr. F.A. Murphy, Davis, CA.)

chain reaction (RT-PCR). Nucleic acid sequences of RVF and CCHF virus may be detected directly in patients' viremic blood by RT-PCR, although caution is warranted when using this technique for CCHF virus because variation in nucleotide sequences among strains may require more than a single primer pair to detect all viruses. The use of PCR or the slower virus isolation techniques is essential for diagnosing fatal CCHF cases because these patients usually fail to develop detectable antibody. The antigen-capture enzyme-linked immunosorbent assay (ELISA) can be used to detect viral antigen in the patient's acute serum in 5 to 6 hours, as compared with days for the classical virus isolation method, but is less sensitive. However, the assay is of value for the more severe CCHF cases because of the higher titer and prolonged viremia.

In convalescing patients, ELISA is used to detect IgM in serum and CSF (RVF) and to detect a rise in IgG level in paired acute and convalescent sera. In the case of RVF, the neutralization test is the most specific for detecting virus-specific antibody. The results of each or a combination of these laboratory tests can be supported by immunohistochemistry and in situ hybridization analysis of autopsied tissues, preferably mononuclear phagocytes, endothelial cells, and hepatocytes. The laboratory should be notified that specimens originate from a hemorrhagic fever patient, so that appropriate biosafety measures can be taken.

## TREATMENT AND PROGNOSIS

Usually, treatment of a patient with hemorrhagic fever must be initiated before an etiologic diagnosis is made.<sup>46</sup>

There is no established treatment for RVF, although in experimental animals ribavirin and passive antibody can be protective.<sup>47</sup> In addition, recombinant or lymphoblastoid human IFN- $\alpha$

doses of  $5 \times 10^3$  units/kg body weight daily for 5 days suppresses RVF viremia and disease in rhesus monkeys.<sup>48</sup>

Ribavirin is effective for inhibiting CCHF viral replication in cell culture and in animal models.<sup>38,39,49–51</sup> It is believed to be helpful in treatment of human disease, but clinical trials have not been done.<sup>19,52,53</sup> Limited studies suggest that CCHF immune serum is beneficial when administered intravenously in a dose of 250 mL over 1 to 2 hours on successive days, and when given early in infection.<sup>54,55</sup> The evidence is based on observed clinical improvement, but the study did not include placebo control patients.

If viral hemorrhagic fever is suspected in the tropics and laboratory confirmation is not available, it would be reasonable to use intravenous ribavirin at 30 mg/kg body weight for one dose, then 16 mg/kg every 6 hours for 4 days, then 8 mg/kg every 8 hours for 6 days.<sup>56,57</sup> High-risk contacts who develop fever could be treated promptly with ribavirin. Intravenous and oral ribavirin can be obtained in the United States from ICN Pharmaceuticals, Inc. (Costa Mesa, CA) after an Investigational New Drug (IND) application number has been secured from the Food and Drug Administration, Division of Antiviral Drug Products (301-827-2335, or after hours, 202-857-8400). Although there are promising therapeutic candidates, the only measures that are routinely administered for hemorrhagic cases are supportive therapies focused on hematologic and fluid imbalances.

## PREVENTION AND CONTROL

Nosocomial spread of CCHF is prevented by maintaining hemorrhagic fever patients in isolation and using universal precautions.

All patients should be assumed to have a communicable disease until proved otherwise. Local and national health authorities should be notified immediately. Patients should be placed in isolation and universal precautions used by medical and nursing staff, including gown, foot covers, mask, double gloves, and needle precautions. The health-care workers should use respirators if this protection is available.

Inactivated and live attenuated vaccines for RVF have been developed by the U. S. Department of Defense for human use. Most experience has been with the inactivated vaccine, which has been nonreactogenic, induces neutralizing antibodies, and protects laboratory workers.<sup>35</sup> The live-attenuated vaccine that has been inoculated into 60 humans seems to be safe and induces neutralizing antibodies, although the database is obviously small. However, neither of these vaccines is currently available.

Prevention and control of RVF entails vaccination of sheep and cattle in enzootic areas. Livestock serve as amplifying hosts, and their immunization is the key to the prevention of amplification and transmission. Both inactivated and attenuated RVF vaccines have been used in livestock. There is limited availability of most vaccines except two South African products: the live Smithburn neurotropic strain is poorly immunogenic in cattle and causes abortion and fetal abnormalities in pregnant ewes. The manufacturer recommends the inactivated vaccine for cattle. A mouse brain-derived vaccine for CCHF is used in Bulgaria but is not available outside that country.<sup>15</sup> During epizootics, to avoid exposure to virus in the blood, farmers should not slaughter and butcher sick animals, and dead animals

should be buried. Control of mosquitoes is usually impractical, but personal protective measures may be helpful. The epidemic of 1987 in Mauritania was predicted and illustrates the risk of new dam construction with subsequent flooding of large areas in RVF epizootic regions.

Prevention and control of CCHF are achieved by control of *Hyalomma* ticks. Farmers, soldiers, campers, and abattoir workers should be taught to remove ticks in a timely fashion and without crushing them. In endemic areas, a measure of tick control has been achieved by environmental sanitation of underbrush habitats. Acaricides may be useful on domestic animals to control CCHF-infected ticks if used 10 to 14 days prior to slaughter or export of animals from enzootic regions. The use of gloves by abattoir workers has been suggested in order to prevent direct contact of skin with viremic blood of sheep and cattle, but may be difficult to institute in practice.

## Hantavirus Infections

C. J. PETERS  
JAMES N. MILLS  
CHRISTINA SPIROPOULOU  
SHERIF R. ZAKI  
PIERRE E. ROLLIN

### INTRODUCTION

Hantaviruses are rodent-borne agents with a broad geographic distribution in the Americas, Asia, and Europe (Table 68-1). They cause inapparent, chronic infections of rodents and spread to humans through infectious urine, saliva, or feces (Fig. 68-1). The human host suffers one of two major diseases: hemorrhagic fever with renal syndrome (HFRS) or hantavirus pulmonary syndrome (HPS). HFRS is mainly an

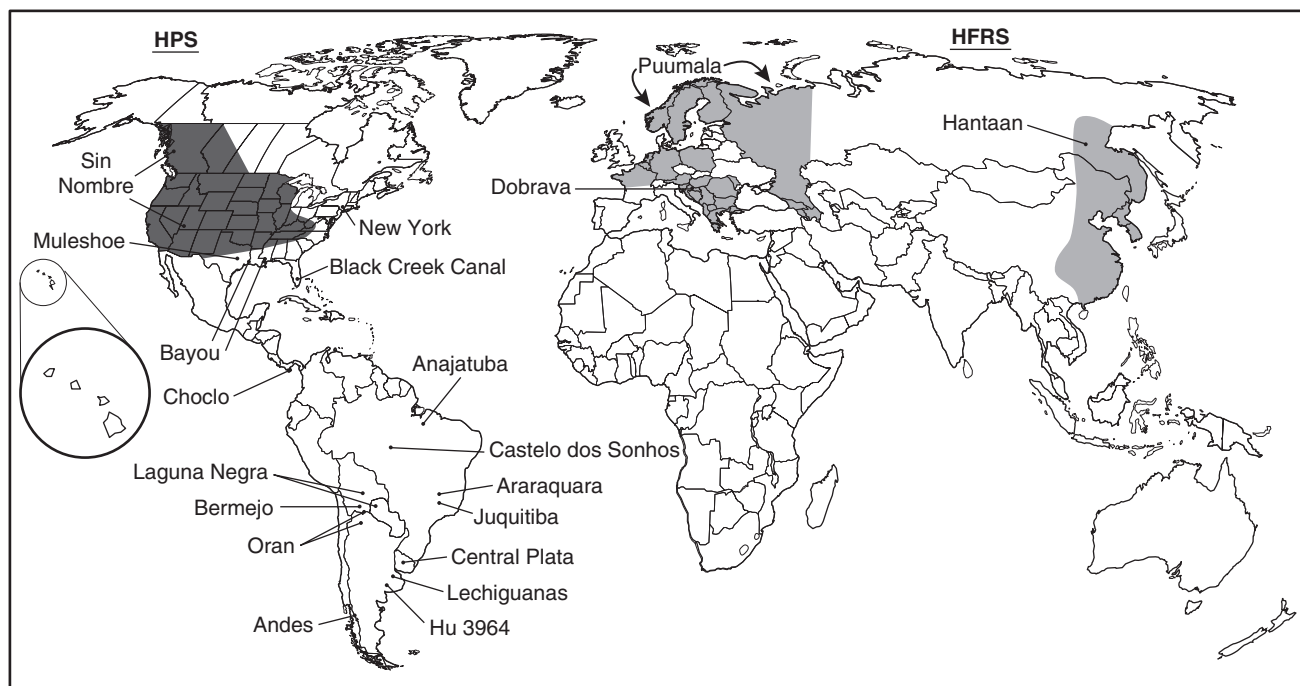

Old World disease, and HPS to date has been encountered only in the Americas. With the exception of Andes virus in Argentina and southern Chile, interhuman transmission of hantaviruses has never been established. The viruses are virtually noncytopathic, and disease is believed to be largely immunopathologic. Prevention rests on rodent avoidance when feasible, but candidate vaccines for HFRS are being tested. Supportive management is important to survival. The viruses are sensitive to the antiviral effects of ribavirin in cell culture, and that drug is an adjunct in the therapy of severe HFRS.

### AGENTS

#### Description

Hantaviruses were first discovered because of an interest in the presumed viral etiology of HFRS. Early work in 1930 to 1950 in Manchuria and the Soviet Union, centered on human studies, suggested a viral agent, but it was not until Hantaan virus was isolated by passage in the suspected rodent reservoir and identified with convalescent serum from HFRS patients that a reliable experimental system was obtained.<sup>1,2</sup> Isolation in cell culture led to the characterization of Hantaan and related viruses and the demonstration that they formed a new genus, *Hantavirus*, within the family *Bunyaviridae*.<sup>3,4</sup> The distinctive syndrome associated with several American hantaviruses was not discovered until 1993.<sup>5</sup>

Hantaviruses presumably originated as parasites of the order *Rodentia*. Their phylogeny corresponds to that of their rodent hosts, suggesting the divergence of the viruses of

Hantaviruses

- Hantavirus pulmonary syndrome (HPS)
- Hemorrhagic fever with renal syndrome (HFRS)

Table 68-1 Hantaviruses, Their Reservoirs, and Hantavirus Diseases

Rodent Reservoir Subfamily	Rodent Reservoir	Virus	Disease	Disease Distribution
Murinae	<i>Apodemus agrarius</i>	Hantaan	HFRS	Asia
	<i>Apodemus agrarius</i>	Saaremaa	HFRS	Balkans
	<i>Apodemus flavicollis</i>	Dobrava	HFRS	Balkans
	<i>Apodemus peninsulae</i>	Amur	HFRS	Far eastern Russia
	<i>Bandicota indicus</i>	"Thailand"	Not known	—
Arvicolinae	<i>Rattus norvegicus</i>	Seoul	HFRS	Asia, elsewhere
	<i>Clethrionomys glareolus</i>	Puumala	HFRS	Europe
	<i>Clethrionomys rufocanus</i>	Puumala-like	Not known	—
	<i>Lemmus sibiricus</i>	Topografov	Not known	—
	<i>Microtus arvalis/Microtus rossiameridionalis</i>	Tula	Not known	—
Sigmodontinae	<i>Microtus californicus</i>	Isla Vista	Not known	—
	<i>Microtus fortis</i>	Khabarovsk	Not known	—
	<i>Microtus ochrogaster</i>	Bloodland Lake	Not known	—
	<i>Microtus pennsylvanicus</i>	Prospect Hill	Not known	—
	<i>Bolomys obscurus</i>	Maciel	Not known	—
	<i>Calomys laucha</i>	Laguna Negra	HPS	Paraguay, Bolivia
	<i>Oligoryzomys flavescens</i>	Lechiguanas	HPS	Central Argentina
	<i>Oligoryzomys longicaudatus</i>	Andes	HPS	Southwestern Argentina
	<i>Oligoryzomys microtis</i>	Rio Mamore	Not known	Bolivia
	<i>Oryzomys palustris</i>	Bayou	HPS	Southeastern United States
	<i>Peromyscus leucopus</i>	New York-1	HPS	Eastern United States
	<i>Peromyscus maniculatus</i>	Sin Nombre	HPS	United States and western Canada
	<i>Reithrodontomys megalotis</i>	El Moro Canyon	Not known	—
	<i>Reithrodontomys mexicanus</i>	Rio Segundo	Not known	—
	<i>Sigmodon alstoni</i>	Cano Delgadito	Not known	—
	<i>Sigmodon hispidus spadicipygus</i>	Black Creek Canal	HPS	Southern Florida
	<i>Sigmodon hispidus texianus</i>	Muleshoe	HPS	Texas, United States
	<i>Oligoryzomys nigripes</i>	Juquitiba	Not known	Southeastern Brazil
	<i>Peromyscus boylii</i>	Limestone Canyon	Not known	Southwestern United States, Mexico

HFRS, hemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome.

America and Eurasia more than 20 million years ago. Little is known of the possibility of hantaviruses of other animals, although it is believed that at least one (Thottapalayam virus) may be a virus of a shrew (*Suncus murinus*, order Insectivora).<sup>6</sup>

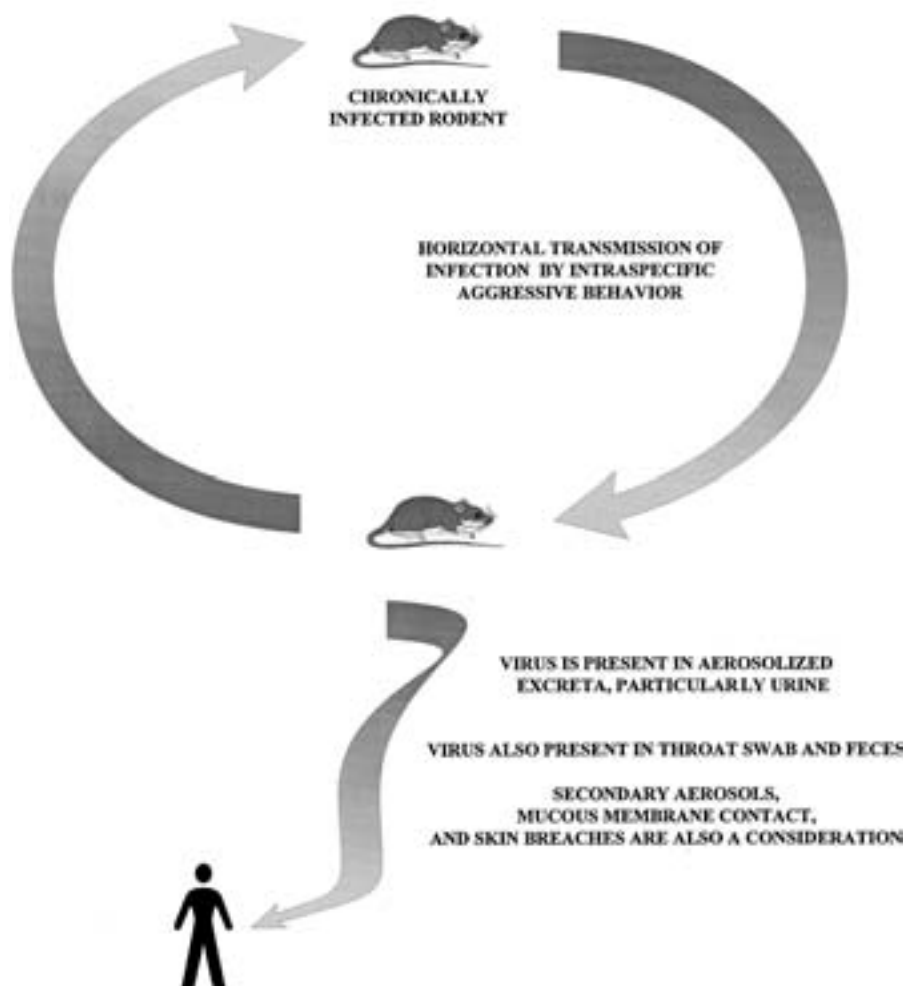

### Morphology

Hantavirus morphology is typical of the members of the Bunyaviridae family, with the virus particles being generally spherical although polymorphic. Elongated particles have also been observed.<sup>7,8</sup> Virus particle size varies from 70 to 120 nm with a dense core containing the riboprotein structures and surface glycoproteins embedded in the lipid bilayer envelope.

### Replication

Hantaviruses are enveloped RNA viruses with a three-segmented negative-sense genome. The segments are designated as S (small, 1600 to 2060 nucleotides), M (medium, approximately 3700 nucleotides), and L (large, 6500 to 7000 nucleotides).<sup>3-9</sup> "Negative sense" signifies that the RNA genome is complementary to the messenger RNA (mRNA) coding for the viral proteins. The naked RNA genome is not infectious. An infectious virus unit requires that viral RNA be encapsidated by the nucleoprotein (N), forming the nucleocapsid core associated with the L viral polymerase protein. To form a mature virus, this unit is then enveloped by a lipid bilayer membrane derived from the host cell.

## Hantaviruses

**FIGURE 68-1** Transmission cycle of hantaviruses. The virus chronically infects its specific rodent host and is spread to other rodents horizontally. Virus shedding on mucosal surfaces is responsible for maintenance (usually an infected rodent bites or has other close contact with another of the same species) and for human infection (probably by aerosolization of virus-laden urine as it is shed, although other possibilities exist). Humans are a dead end in virus transmission, but a single hantavirus epidemic showed person-to-person spread. (Courtesy of K. Wagoner.)

Embedded in the membrane are the two surface glycoproteins, G1 and G2.

The coding strategy for each segment is simple. The S segment encodes the nucleocapsid N protein (molecular weight, 48 kD); the L segment, the polymerase L protein (250 kD); and the M segment, the two glycoproteins, G1 (72 kD) and G2 (54 kD). No nonstructural proteins (NSs or Nsm in analogy with other Bunyaviridae) have been detected in infected cells although there is evolutionary evidence for the existence of an NS equivalent in some hantaviruses.<sup>10</sup>

Infection is initiated by attachment of the virus to the cell, presumably mediated by the virus surface glycoproteins after interaction, in the case of the HPS viruses, with  $\beta$ -integrins.<sup>11</sup> Viral replication is initiated after virion uptake by the infected cells and release of the viral ribonucleoprotein cores into the cytoplasm. Each negative-strand virus RNA segment is transcribed by the virion-associated polymerase (L) to produce a functional mRNA. The relative amounts of the mRNAs synthesized are inversely proportional to their length. Thus, S mRNA is the most abundant and L mRNA the least. A simple

explanation may be that the transcription elongation process is discontinuous with the polymerase pausing and possibly prematurely terminating at specific sites along the genome. The longer the gene, the higher the possibility of the presence of pausing sites. The 5' ends of all three mRNAs are capped and contain a nontemplated guanine (G) residue. A prime-and-realign model has been proposed for the initiation of transcription of the hantaviruses.<sup>12</sup> The termination at the 3' ends of the mRNAs is not the same for each template RNA segment. Hantavirus mRNAs may be stabilized by a stem-loop structure that forms at the 3' noncoding region and initially none of the mRNAs were believed to be polyadenylated, although recent studies have reported that the Sin nombre virus (SNV) M mRNA is polyadenylated.<sup>13</sup> The three mRNAs are transcribed in the infected cell cytoplasm, and their translation is directly coupled to the transcription process.

The ratio of the individual virus proteins synthesized reflects the relative abundance of the virus mRNAs, with the N the most abundant protein. Two of the mRNAs, N and L, are translated on free ribosomes. The GPC mRNA is translated

on membrane-bound polysomes. The GPC precursor molecule is cotranslationally cleaved to produce the G1 and G2 glycoproteins. Both glycoproteins are typical class 1 proteins with the N terminus exposed at the surface of the virion and the C terminus anchored in the membrane.<sup>9</sup> Four potential N-glycosylation sites are conserved among all hantavirus proteins, three of which are located in G1 and one in G2 protein. An additional feature conserved in all hantaviruses is the high number of cysteine residues present in both glycoproteins (57 in total). The cysteine-rich nature of the two glycoproteins may play a role in their complicated higher-order structure.

The mechanisms by which the virus switches from the RNA transcription to the replication mode are not known. Each segment of the RNA genome possesses conserved termini capable of forming panhandle structures that may be involved in initiation of encapsidation and as binding sites for the virus RNA polymerase. The terminal complementarity is incomplete with a non-base-paired bubble present at nucleotides 9 and 10,<sup>14</sup> which may play a role in the regulation of transcription and replication. The main switch from transcription to replication mode is thought to involve increasing concentrations of N protein, leading to more efficient RNA encapsidation. This allows the polymerase to read through the transcription termination signals and synthesize the full-length virion RNA templates. One powerful tool for manipulation of genomes of RNA viruses has been the development of “reverse genetics” (reconstruction of infectious virus from plasmids). Although this tool has been developed for several other negative-sense segmented RNA viruses (e.g., influenza), it has proved difficult to develop for hantaviruses. However, the recent rescue of hantavirus minigenomes will allow mutational analysis of the termini of the viral genome and shed light on transcription-replication requirements.<sup>15</sup>

Assembly of the virus begins once sufficient amounts of the structural proteins have been synthesized and genomic RNA has been replicated. In the endoplasmic reticulum, the two glycoproteins form heterodimers and exit to the Golgi.<sup>16</sup>

Localization and accumulation of the two proteins in the Golgi are thought to be the reason hantavirus maturation occurs in the Golgi complex rather than at the cell surface, which is the more common virus maturation site.<sup>9</sup> In addition to the virus glycoproteins, the virus nucleocapsid protein can be detected in the proximity of the Golgi, consistent with virus assembly in the Golgi. The long cytoplasmic tail of G1 has been speculated to interact with the underlying nucleocapsid cores and promote assembly of mature virion particles. The cytoplasmic vesicles carrying the virions then fuse with the plasma membrane, allowing extracellular release of the mature virions. However, in addition to Golgi maturation, some hantaviruses, specifically Sin Nombre and Black Creek Canal viruses in Vero-E6 cells,<sup>8,17</sup> may also mature at the cell surface (Fig. 68-2). Further studies have shown that the majority of the SNV G1 and G2 glycoproteins are localized in the Golgi complex when expressed from a full-length GPC clone or in SNV-infected cells, in agreement with data for other members of the family Bunyaviridae, including the Old World hantaviruses.<sup>18</sup> However, the SNV glycoproteins are also be detected at the cell surface at advanced times post-transfection or postinfection. After reaching the cell surface, the glycoproteins can recycle back to the Golgi. An additional major pool of G1 is also detected in late endosomes and

**FIGURE 68-2** Electron micrograph of Sin Nombre virus (SNV) grown in Vero-E6 cells, showing virus particle budding from the cell surface (arrow). Tubular projections (arrowheads) extended from the plasma membrane of infected cells and were specific for SNV antigens by immunogold labeling. Bar = 100 nm. (Courtesy of C. S. Goldsmith and L. H. Elliott.)

lysosomes, providing a mechanism by which hantaviruses down-regulate glycoprotein levels and virus maturation. In addition, the nucleocapsid protein N interacts with actin microfilaments, which may contribute to the morphogenesis of the virus particles.<sup>19</sup>

### Virus Phylogenetics

Because hantaviruses are segmented negative-strand RNA viruses, they have potential for rapid generation of genetic diversity based on their predicted high RNA polymerase error rate and the possibility of genetic reassortment (mixing of genomic RNA segments between viruses). Experimental studies have shown that genetic reassortment can occur among hantaviruses but are limited to closely related hantaviruses.<sup>20</sup> In addition, the potential for virus genetic variation via homologous recombination has been shown for hantaviruses.<sup>21</sup> Homologous recombination occurs in positive-sense RNA viruses (e.g., poliovirus) but has not been previously observed in negative-sense RNA viruses and provides another mechanism by which hantaviruses could have achieved genetic diversity and evolution.

Phylogenetic analysis of the hantavirus genome sequence differences reveals a complex evolutionary pattern, with multiple virus genetic lineages present in Asia, Europe, and the Americas. There is a good correlation between viral phylogeny and the rodent phylogeny, indicating that the viruses and their rodent reservoirs have coevolved over thousands of years. That makes hantaviruses very “old” although recently discovered.<sup>22</sup> The hantaviruses associated with Murinae, Arvicolinae, and Sigmodontinae subfamily rodents form three distinct phylogenetic groups. Viral lineages correlate with the phylogeny of the reservoir, and any relation to geographic location is based mainly on the distribution of the rodent host. The number of hantaviruses that have been recognized over the past decade has increased exponentially.<sup>22</sup> It is now difficult to distinguish between a new subtype of the same virus species and a new virus species. Combinational analysis of virus-host genetics

and patterns of virus maintenance and transmission will more precisely define virus species and their pairing with rodent host primary reservoirs.

### Host Range and Virus Propagation

Hantaviruses persistently infect their specific rodent hosts and occasionally spill over into other species. No disease symptoms are observed in the infected rodent reservoirs that maintain and transmit the viruses. The restricted host range of the hantaviruses is also evident when attempting to establish experimental infections of rodents in the laboratory. Host species or even subspecies can greatly alter the outcome of experimental virus infection, as can viral dose and portal of entry. Although experimental infection of the rodents results in the presence of viral antigens in different tissues, there is little resemblance to the human disease. For example, intracerebral inoculation of newborn mice with many hantaviruses will cause fatal disease, but the cause of death is meningoencephalitis rather than renal or pulmonary disease. Currently, there is no useful animal model for study of HFRS despite the large number of rodent species and several nonhuman primate species that have been tested.<sup>23</sup> Recently, infected hamsters have been found to develop typical HPS, opening the way for many useful experiments in pathogenesis and therapy.<sup>24,25</sup> Virus isolates have been obtained from infected rodent samples but usually with great difficulty; successful attempts have often involved a number of blind passages of material in the rodent host prior to virus adaptation to tissue culture.<sup>26–28</sup> This property is not understood and cannot readily be explained by genetic adaptation.<sup>14,29</sup> It has limited quantitative studies of virus excretion, clinical viremia of patients, and other important facets of hantavirology. Human isolates have been even less commonly obtained, presumably because of the immunopathologic nature of hantavirus disease<sup>30</sup>; indeed, there is only a single human isolate of an HPS-causing virus,<sup>31</sup> although genetic evidence convincingly links the rodent viruses to the human disease.<sup>5,14</sup> Once adapted to cell culture, the growth of hantaviruses is still poor, but several cell lines and primary cells are susceptible after initial adaptation to culture.<sup>32</sup> Vero-E6 cells are a commonly utilized cell line in which most hantaviruses propagate well without killing the cell or producing overt cell damage. Endothelial cells are the primary targets in naturally acquired hantavirus infections<sup>33,34</sup>; they are also readily infected in vitro with no evident cytopathic effect.<sup>35</sup> Indeed, infection of primary endothelial cells does not produce changes in permeability or electrical conductance.<sup>36</sup>

## EPIDEMIOLOGY

### Transmission Cycle

Chronic infection of a specific rodent host and persistent shedding of virus in urine, feces, and saliva is the key to the maintenance of hantavirus infections in reservoir populations as well as in human infection. Although other genera in the family Bunyaviridae have arthropod vectors, *Hantavirus* has no identified intermediate host; early epidemiologic data suggested participation of mites, but the virologic data are unconvincing.<sup>37,38</sup> Additionally, unlike the situation with

other HF viruses, particularly some rodent-borne arenaviruses, there is no known vertical transgenerational backup mechanism to ensure virus survival<sup>39</sup>; presumably the broad geographic distribution suffices.

Viral maintenance seems to be achieved by intraspecific transfer of virus among adult animals. Field studies with Sin Nombre virus in the American Southwest revealed a J-shaped curve of antibody prevalence with age in *Peromyscus maniculatus*.<sup>40</sup> The most likely explanation is that the young of infected females are protected by maternal antibody, which is lost within a few weeks.<sup>41</sup> Infection is acquired horizontally after weaning, and antibody prevalence then rises again. In addition to the positive correlation of age with infection status, field data often indicate that the more combative males are more frequently infected than females, and there is a positive correlation between infection and the presence of scars or wounds.<sup>40,42,43</sup> All or parts of this epizootiologic pattern have been observed in field studies of Sin Nombre, Black Creek Canal, El Moro Canyon, Puumala, and Seoul viruses in their respective hosts.<sup>40,42,44–47</sup> Laboratory rats are susceptible to infection by Hantaan, Seoul, and Puumala viruses by either aerosol or intramuscular routes, but infectious doses by the latter route are about 100 times lower than those required to infect by aerosol.<sup>48</sup> Thus, the hantaviruses appear to spread primarily horizontally among their rodent reservoirs, and aggressive encounters among adult male animals are an important mechanism of transmission.

Large year-to-year fluctuations in population density are a typical characteristic of rodents of many species. Northern Hemisphere arvicoline or voles (including the reservoir for Puumala virus) undergo fairly regular population cycles with a 3- to 4-year periodicity. The causes of these cycles are poorly understood.<sup>49,50</sup> Although regular cyclic population fluctuations are not characteristic of rodent populations in the Southern Hemisphere or northern tropics, periodic dramatic, temporary increases in population density (“irruptions”) occur. These events are often tied to unusual climatic events that result in temporary but highly favorable conditions for alimentation and reproduction. Outbreaks of human disease may be associated with these conditions. For example, the HPS outbreak in the American Southwest in 1993 was preceded by an El Niño southern oscillation event that resulted in unusually warm winters with high rainfall in areas of the Southwest. An increase in numbers of HPS cases in the same area of the southwestern United States in 1998 to 2000 was associated with an El Niño event in 1997.<sup>51,52</sup> An outbreak of HPS in southern Chile in 1997 appears to have been precipitated by dramatic increases in population density of the reservoir for Andes virus.<sup>53</sup> The cause of this irruption is unclear, but it may be related to the unusually mild winter that preceded the irruption or to the flowering of a species of bamboo across a wide area of southern Chile during several of the preceding years. This phenomenon occurs approximately every 40 years, may last 5 to 7 years, and provides abundant food for the graminivorous rodent reservoir *Oligoryzomys longicaudatus*.<sup>54</sup>

The prevalence of infection in reservoir populations also varies both temporally and spatially. Long-term field studies in Sweden have shown that prevalence of antibody to Puumala virus in populations of bank voles (*Clethrionomys glareolus*) is highest in the spring and is positively correlated

with vole population density the previous fall and spring (delayed density dependence).<sup>46</sup> This is likely to be a general pattern for viruses transmitted by horizontal mechanisms transmitted<sup>55</sup>. The spring population consists of older individuals born during the previous season that have survived the winter, while the fall population consists of a high proportion of young of the year that are more likely to be unexposed or very recently exposed and have not yet developed antibody. The delayed density-dependent function is also intuitive, since crowded conditions offer greater opportunities for intraspecific contacts, aggressive or otherwise. The year-to-year incidence of human disease is also correlated with the density of voles in Russia and in Scandinavia.<sup>46</sup> In the United States, long-term studies of rodent reservoirs of hantaviruses<sup>55</sup> indicate that regulation of hantavirus transmission in host populations and subsequent risk of human infection are associated with what has been called a "trophic cascade."<sup>56</sup> Favorable climatic conditions (such as an El Niño event in the southwestern United States) result in improved environmental conditions (benign physical environment, abundant plant and animal food), and improved reproductive success. Stress and increased interactions associated with crowded conditions lead to increased viral transmission and higher prevalence of infection in host populations. The greater numbers of infected mice and immigration of mice away from overcrowded population centers result in increased risk to nearby human populations.

Favorable environmental conditions might be brought about not only by favorable climatic events or periodic bamboo blooms. Human disturbance to native ecosystems may create conditions that favor certain opportunistic species, some of which are hantavirus reservoir species, resulting in population irruptions in those species.<sup>57,58</sup>

Infection in reservoir animals may be highly focal. Sin Nombre virus infection in the American Southwest varied between 0% and 50% in local deer mouse populations sampled nearly simultaneously.<sup>40</sup> Human disease may be associated with specific geographic localities where reservoir population densities and prevalence of infection are highest.<sup>59,60</sup>

A variety of nonreservoir species has been found to have antibody reactive with hantavirus antigens.<sup>61,62</sup> This is especially true under epizootic conditions, when high rodent density and high prevalence of infection among reservoir populations increase the chance of encounters among infected hosts and other animals that share their habitat. Carnivores that feed on infected rodents may also become infected, as evidenced by antibody in domestic cats in Europe<sup>63</sup> and the United States (T. G. Ksiazek and colleagues, unpublished data) and coyotes in the United States (C. Bond, personal communication, 1997). Nevertheless, infection in nonhost mammals usually does not result in disease (humans being a notable exception), and is not likely to be epidemiologically important. In general, only the natural host is capable of supporting chronic infection and shedding large quantities of virus into the environment.

Human infection is thought to occur mainly by the aerosol route.<sup>64-66</sup> There are a number of well-documented instances in the laboratory, as well as in domestic and occupational settings. Although virus is found in throat swabs and feces of infected rodents, by far the largest quantity of excreted virus is found in urine, which is also the most likely

material to generate aerosols.<sup>23</sup> Secondary aerosols from disturbing shed excreta or secretions are often suggested as routes of transmission to humans, and dusty areas are often seen as particularly risky.<sup>37,64,67</sup> However, it would be unusual to find sufficient energy applied to generate the 1- to 5- $\mu$ m particles that would remain suspended in the air and be inhaled deep into the lung. Vacuum cleaners, with their beaters and forced air flow, might be an exception. Interestingly, most enveloped viruses are more stable in aerosols in conditions of low relative humidity. The role of mucous membrane contamination by larger secondary particles and other routes also deserve further study. Because of the much greater infectiousness of hantaviruses by parenteral exposure than by aerosols, bites are potentially very dangerous.<sup>48</sup> At least two cases of HFRS have been attributed to rodent bite.<sup>68,69</sup>

### Infection of Humans

It is obvious that exposure to rodents chronically shedding a hantavirus is a prerequisite for human disease, but determinants of the probability of human infection are poorly understood, particularly in interepidemic periods. Most epidemics occur in the setting of high rodent populations with a relatively high prevalence of rodent infection. Within an epidemic area, individual risk is also correlated with exposure to infected rodents.<sup>59</sup> However, it is not widely appreciated that at any given time there are many infected rodents and relatively very few human infections. In the southwestern United States in 1993 a significantly greater number of rodents were trapped in case households (median number, 17.1; seroprevalence, 19.3%) than in nearby (median number, 12.8; seroprevalence, 19.4%) or more distant (median number, 8.3; seroprevalence, 25.0%) control households; thus, even control houses often had positive rodents. Similarly, in interepidemic periods, there are few human cases considering the number of infected rodents that may be in proximity to humans.

One important factor is the small amount of aerosol generated from a drop of liquid such as urine falling on a surface. For example, a drop of bacterial culture falling 3.5 cm to a surface generates only 10<sup>-8</sup>- to 10<sup>-9</sup>-mL particles.<sup>70</sup> Little is known about the stability of hantaviruses in aerosols, solutions, or dried particles of rodent urine or even of defined menstruums. Obviously, rodent urine composition and pH will depend on the rodent's diet and whether or not it is a species that normally secretes a urinary protein. Another major variable may be the amount of virus shed. The concentration of Hantaan virus in secretions or excreta from recently infected reservoir rodents is 100- to 1000-fold higher than that found later, and the maximum efficiency of intraspecies transmission between caged *Apodemus agrarius* reservoirs occurs between 10 and 35 days postinoculation.<sup>38</sup> Similarly, the ability of bank voles infected by Puumala virus to infect pristine voles housed briefly in the same boxes is much greater 14 through 28 days following inoculation, coinciding with the period of detectable virus shedding in the saliva.<sup>71,72</sup> Black Creek Canal virus has similar properties in its reservoir.<sup>73</sup> Thus, human risk is complicated and inefficient because of a mosaic of factors, including the nature of rodent exposure, the infection status of the rodent, rodent genotype, duration of infection, and probably other factors not yet fully understood.

## Geographic Distribution

Because of the long phylogenetic association of hantaviruses with their rodent hosts, their geographic distribution can best be understood in terms of the distribution of reservoir species. Hantaviruses are associated with three subfamilies of rodents of the family Muridae (see Table 68-1).

Diseases caused by the viruses associated with the Old World rats and mice (subfamily Murinae) are commonly found in Asia, with Hantaan virus being the most important. This virus causes severe HFRS and is probably the virus responsible for the cases from the Amur River valley (Songo fever) during the Russo-Japanese conflict in the 1930s. It also is responsible for most of the diseases in the Russian Far East (hemorrhagic nephrosonephritis, Churilov disease), Korea (Korean hemorrhagic fever), and China (epidemic hemorrhagic fever). Hantaan virus is found in the Balkans, but severe HFRS that has been genetically studied there has been caused by Dobrava virus.<sup>74</sup>

Seoul virus is found worldwide, wherever its host *Rattus norvegicus* has invaded from its original central Asian home,<sup>75</sup> but most convincing reports of human disease come from Korea,<sup>76,77</sup> Russia, and China,<sup>78,79</sup> where it is associated with moderately severe HFRS that occurs with an urban and winter preponderance reflecting the reservoir habits. The infrequent diagnosis of HFRS in many other areas of the world where *R. norvegicus* occurs is not explained. For example, only three suspected cases have been reported from the United States.<sup>80</sup> Lesser contact with rats may be an important variable because human seroprevalence in the United States is only 0.35% when stringent testing criteria are used.<sup>81</sup> Case-finding is probably also inadequate. There is little overall phylogenetic difference in the Seoul virus strains analyzed, although we have no way of knowing if there are critical mutations.<sup>82</sup> Disease has been associated with laboratory rat colonies that have become infected with Seoul virus in Belgium, the United Kingdom, Japan, China, Korea, and likely other countries.<sup>83</sup> U.S. rat colonies have been free of hantavirus infection so far, perhaps as a result of the common practice of caesarean derivation and barrier rearing of breeding stock, as well as the lack of contamination of transplantable cell lines.<sup>84,85</sup>

Dobrava virus is associated with *Apodemus flavicollis* in the Balkans and has been associated with human disease there.<sup>86,87</sup> Saaremaa virus also occurs in the Baltic area but is associated with *Apodemus agrarius* and causes a milder form of HFRS.<sup>21</sup> Amur virus, associated with *Apodemus peninsulae*, causes HFRS in eastern Russia and perhaps other areas of East Asia.<sup>88</sup> The other recognized virus from murine rodents is Thailand virus, identified in bandicoots in that country. There is considerable seropositivity among bandicoots, and they are an increasing urban pest problem, but no disease association has been made.<sup>89,90</sup>

The subfamily Arvicolinae (voles and lemmings) is distributed throughout the Northern Hemisphere although only arvicoline species from Europe have been associated with human disease. Puumala virus, whose primary host is the bank vole, *Clethrionomys glareolus*, is associated with nephropathia epidemica (NE), a relatively mild form of HFRS in Scandinavia, western Europe, and European Russia. None of a variety of other hantaviruses associated with arvicoline species in Europe, Asia, and North America are definitively associated

with human disease, although intensive studies have not been done.

All the viruses known to cause hantavirus pulmonary syndrome are associated with murid rodents of the subfamily Sigmodontinae (New World rats and mice). Although most HPS in North America has occurred in the western United States and Canada, sporadic cases have been confirmed in several eastern states, including Vermont, New York, Pennsylvania, Virginia, West Virginia, North Carolina, Florida, and Louisiana. Most cases are associated with Sin Nombre virus and *P. maniculatus*. Although the deer mouse is one of the most common and widespread rodents in North America, the ranges of other host species associated with HPS are more restricted. The white-footed mouse (*Peromyscus leucopus*) is restricted to the eastern United States; the rice rat (*Oryzomys palustris*) is restricted to the southeastern United States; and the cotton rat is restricted to the Southeast and South Central United States, Central America, and northern South America.

HPS has been confirmed in many Latin American countries (see Table 68-1). Indeed, it appears that hantaviruses in sigmodontine rodents are present wherever one seeks them in the Americas. Serendipitously, as a result of long-term studies of rodents associated with Junin virus on a small area of the central Argentine pampa,<sup>91</sup> thousands of frozen rodent serums and tissues have been archived. Screening of these samples resulted in the identification of three distinct hantaviruses from three sympatric rodent species.<sup>92</sup> The existence of this bank of frozen sera also allowed investigators to conclude that Laguna Negra virus, a cause of HPS in Paraguay,<sup>93</sup> does not occur in populations of *Calomys laucha* from central Argentina.<sup>94</sup> Thorough serologic surveys of sigmodontine rodents in other parts of Latin America will doubtless detect infection, and subsequent reverse transcription (RT)-polymerase chain reaction (PCR) tissue studies reveal the existence of numerous additional hantaviruses.

## Epidemiologic Risk Factors

The circumstances that bring infectious rodents into contact with humans have received relatively little formal study once etiologic diagnosis became possible. HFRS classically has been a disease of rural populations and has been associated with agricultural workers and the military.<sup>37,95,96</sup> Cases occur year-round and usually are sporadic, but about 10% are in clusters. The peak incidence varies geographically and can be summer or fall, or, as in Korea, have dual peaks in spring and fall.<sup>30</sup> This seasonality usually can be related to local factors in ecology, human habits, and the specific reservoir.

For example, in Scandinavia the peak number of cases of Puumala virus infection occurs in the summer, when people enter vacation homes and disturb the bank voles that have entered the cabins; finding rodents in the house and in the cupboards is a significant risk factor.<sup>97</sup> Military personnel in Korea have the maximum risk associated with living in primitive field conditions, sighting rodents around their quarters, and occupying dusty environments.<sup>98</sup> In rural China, adult men working on farms and sleeping outside their homes near their fields had increased probabilities of developing HFRS, and threshing rice was identified as another risk factor.<sup>64</sup> It has been suggested that cats might be protective, might bring infected

rodents into contact with humans, or might be a marker for homes in which cats were kept because of the presence of rodents; studies have generally shown cats to be a risk factor or to be neutral, and there is no indication that cats become chronically infected or shed virus during acute infection.<sup>64,99</sup>

Studies of HPS in the southwestern United States during 1993 found rural residence and an excess of small rodents trapped by standardized methods in and around case households to be the major risk factors.<sup>59,100</sup> If the number of rodents found during the study was controlled for, agricultural activities and cleaning peridomestic structures were still risk factors, but reported sighting or trapping of rodents in the home was not a significant variable. Most houses were in piñon-juniper habitats, but house type or measures of environmental sanitation had no correlation. Interestingly, a history of opening and cleaning uninhabited structures, such as summer cabins, has continued to be a common activity among HPS patients.<sup>101</sup> Recent studies demonstrated a higher prevalence of antibody to Sin Nombre virus among peridomestic populations than among sylvatic populations of deer mice in rural areas of Montana.<sup>102</sup> In South America, HPS has generally been associated with rural living and agriculture.

Risks do not remain constant in a given area. In addition to previously noted changes in rodent populations over time, changing patterns have been reported from Korea and China with sustained, marked increases in the incidence of HFRS in southern Korea and areas of China.<sup>78,103</sup> It is not known to what extent this reflects increased disease incidence, increased reporting, or both.

## DISEASES

Infection of the rodent host is followed by viremia and then an immune response that terminates viremia but leaves a chronic infection with lifelong virus excretion on mucosal surfaces, all with no recognized signs of overt disease. Infection of humans, however, may lead to severe disease at the time of the immune response, but chronic infection does not occur, and virus shedding leading to interhuman transmission is unknown, except with Andes virus. The clinical syndrome that occurs in humans takes two forms: the classic HFRS and HPS.

### Hemorrhagic Fever with Renal Syndrome

#### HFRS Following Hantaan Virus Infection

Typically severe disease has a characteristic progression beginning with fever, which gives way to a brief period of hypotension followed by renal failure and finally diuresis.<sup>96,104–110</sup> (Fig. 68-3). The onset is abrupt, with fever, chills, malaise, myalgia, thirst, and headache. Capillary dilation is evidenced by flushing of the face and neck and by conjunctival and pharyngeal injection. Increased capillary permeability is generalized but most characteristically results in retroperitoneal edema accompanied by severe backache. During this phase, low-grade disseminated intravascular coagulation (DIC) appears and thrombocytopenia develops<sup>111</sup>; the cause is unknown but may reflect endothelial infection by the virus and a hypothesized procoagulant shift in the nonwetting surface of the vessel lining.<sup>35,112</sup> Bleeding is commonly seen in the skin and conjunctivae. Abdominal pain, anorexia, nausea, vomiting, mild cough, hiccough, and dizziness are also frequent.

Proteinuria is usually present. The white blood cell count is normal or slightly elevated, often with a left shift.

After 3 to 7 days, the high fever falls and is replaced by a low-grade fever or normal temperature, and the patient enters the hypotensive phase. There may be only a few hours of transient hypotension or 1 to 3 days of severe clinical shock; kinin activation occurs during this period and is proportional to the severity of the shock.<sup>113</sup> Milder cases have a relative or even absolute bradycardia, but severely affected patients show tachycardia, narrow pulse pressure, and cold moist extremities; the blood pressure may fall to undetectable levels. The patient is usually apprehensive with a clouded sensorium, and nausea and vomiting are severe problems. Proteinuria increases, as does back pain. Hemoconcentration from plasma extravasation may result in a hematocrit of 55% to 65% or higher in severe cases. The urine, which contains red blood cells, white blood cells, and casts, decreases in volume, and the specific gravity moves to 1.010. Platelets reach their nadir, usually below 70,000/ $\mu$ L, and white blood cells are increased, often above 30,000/ $\mu$ L and occasionally reaching leukemoid levels. Careful management with Trendelenburg's position, pressors, and inotropic agents usually results in survival, but some patients die in severe shock during this phase. Because of the marked increase in vascular permeability, including in the lung, large quantities of fluids can be dangerous, and human serum albumin is often given for refractory shock. Cardiovascular measurements during the Korean War showed that patients did not conform to the expected findings in septic shock but rather had a low cardiac output and a high peripheral resistance.<sup>114</sup> Patients in frank shock with peripheral vasoconstriction were often given one to two units of albumin with apparent improvement.

After the hypotensive phase, a period of oliguria occurs with all the complications expected from uremia and electrolyte abnormalities. Platelets begin to rise, but bleeding, including hematuria, hemoptysis, and gastrointestinal hemorrhage, is troublesome during this stage. Fluid is resorbed and the patients may be overexpanded, leading to a high-output state, hypertension, and sometimes fatal pulmonary edema. Dialysis is indicated urgently for overhydration because of the likelihood of pulmonary edema as well as intracranial hemorrhage.

After 3 to 7 days of oliguria, urine output increases and may reach several liters daily. Electrolyte abnormalities and dehydration may threaten the patient during this phase. Urine specific gravity is fixed around 1.010, and the concentrating defect may persist 3 weeks to 3 months.

Other clinical laboratory tests can be useful. The aspartate transaminase (AST) level is usually elevated but not massively except in occasional cases of Seoul virus infection. Electrocardiograms (ECGs) are often abnormal with sinus bradycardia, low voltage, electrolyte changes, or nonspecific ST-T wave findings.<sup>115,116</sup> Atrial arrhythmias are not uncommon, but in spite of the right atrial lesion usually seen at autopsy, there are generally no specific findings on the ECG, although there is one report of elevation of the P-R interval in association with right atrial hemorrhage and dilation.<sup>117</sup> Plain films of the abdomen usually do not show the renal shadows, because of retroperitoneal edema. Magnetic resonance imaging (MRI) may suggest hemorrhage because of the low T2-weighted signal intensity along the outer medulla.<sup>118</sup> Pulmonary infiltrates are not common except in the face of overhydration, but occasionally pulmonary edema or effusions are present even early

**FIGURE 68-3** Schema of clinical course of severe hemorrhagic fever with renal syndrome (HFRS). (Modified from Sheedy JA, Froeb HF, Batson HA, et al: The clinical course of epidemic hemorrhagic fever. *Am J Med* 16:619–628, 1954.)

in disease.<sup>116</sup> The renogram shows patterns consistent with obstruction or tubular damage.<sup>116</sup>

A number of complications of HFRS have been observed. In consonance with the tightly swollen kidneys described at necropsy,<sup>96,119</sup> renal rupture may occur in the oliguric or early diuretic phase of illness and can respond to conservative management or require operative therapy.<sup>120</sup> Abdominal and back pain, signs of retroperitoneal hemorrhage, and abnormal ultrasound examination are present. Transient hypopituitarism and frank intrapituitary hemorrhage have been associated with pituitary apoplexy, abnormal anterior pituitary hormonal responses, delayed diuresis, and late appearance of Sheehan's syndrome.<sup>121</sup> These complications can be suspected by functional tests of the anterior pituitary and confirmed with computed tomography (CT) or MRI of the sella turcica.

Recovery is thought to be complete, but a small proportion of patients with residual abnormalities have left medical observation in all these studies. Interest in sequelae of hantaviruses is high because of an extensive study in Baltimore linking hypertensive chronic renal failure to the presence of Seoul antibodies.<sup>81</sup>

Description of the severe disease provides an excellent framework for understanding the pathogenesis of HFRS but is misleading in identifying the milder forms of Hantaan virus

infection or of the milder renal syndromes associated with other hantaviruses. The spectrum of Hantaan virus infection includes fulminant disease with early death, patients whose clinical course "skips" one or more phases, telescoping of the phases, and very mild disease not readily identified as HFRS.<sup>109</sup>

#### HFRS Following Seoul Virus Infection

Seoul virus causes HFRS in humans and has been responsible for fatal infections in laboratory workers exposed to occultly infected rats, although the overall mortality is low, perhaps 1% or less.<sup>69,122,123</sup> The clinical picture of human disease acquired from wild *R. norvegicus* in Asia differs from that of Hantaan virus infection by its lesser severity and by having more prominent liver involvement.<sup>69,77</sup>

#### Mild HFRS Following Puumala Virus Infection

In Europe most cases of HFRS are caused by Puumala virus and are similar to but much milder than Hantaan virus infection.<sup>124–128</sup> The patient typically has fever, myalgia, malaise, and anorexia. Escalating abdominal pain, perhaps associated with nausea and vomiting, may lead to suspicion of a surgical emergency, but the onset of oliguria or the abnormal results of

urinalysis usually averts operative intervention. Myopia, blurred vision, and even glaucoma have been reported in a significant proportion of patients and are very suggestive of the diagnosis.<sup>128,129</sup> The clinical course usually progresses rapidly through petechiae, mild hypotension, and transient oliguria with recovery. Diuresis and hyposthenuria may be notable and persist into convalescence.

In keeping with the milder clinical course, clinical laboratory abnormalities are fewer, including maximum creatinine levels. Thrombocytopenia is only present in one-half to three-fourths, leukocytosis in one-half of patients. Dialysis is required in fewer than 5% of patients, and mortality is less than 1%. As with Hantaan virus infection, sequelae are uncommon or absent, although hypertension in convalescence has been reported.<sup>130,131</sup>

Puumala virus is known to cause mild or asymptomatic disease based on retrospective serologic data, and some patients have had virtually asymptomatic infection or notable disease without detected renal involvement.<sup>132–134</sup> Occasional patients have shown a dominant neurologic picture clinically suggesting viral encephalitis or other neurologic manifestations, including Guillain-Barré syndrome.<sup>128,135</sup>

## Infection with Other Old World Hantaviruses and Other Syndromes

As mentioned previously, Dobrava virus, associated with the rodent *A. flavicollis*, is a cause of lethal HFRS in the Balkans.<sup>86,87</sup> Some Southeast Asian patients, possibly infected with Seoul virus, have severe hepatitis as well as renal failure, and an initial report suggests the possibility of hantavirus infection in Chinese patients with clinical hepatitis and no markers for hepatitis A through E infection.<sup>136,137</sup> Some viruses from *Microtus* and other Arvicolinae species in eastern Europe and Russia are suspected to cause HFRS; no definite evidence establishes their pathogenicity or spectrum of disease.

## Hantavirus Pulmonary Syndrome

The other major syndrome associated with hantavirus infection is pulmonary rather than renal and was recognized only in 1993<sup>5,138,139</sup> (Fig. 68-4). The pathogenesis is similar to that of HFRS in many ways, but the resultant clinical picture is distinctive (Table 68-2) and is caused by a different set of hantaviruses than HFRS (see Table 68-1).

The disease begins with the abrupt onset of fever, myalgia, and malaise, often accompanied by chills, anorexia, and headache.<sup>138,140–142</sup> The patient's subjective condition worsens with prostration and sometimes prominent gastrointestinal symptoms such as nausea, vomiting, abdominal pain, and diarrhea. Dizziness may be present as well.<sup>141,143</sup> Pharyngitis, rhinorrhea, rash, and cough usually are absent. If patients come in for medical attention because of their extreme discomfort, they usually will be sent away because of the lack of objective findings. This prodromal stage lasts 3 to 5 days (range, 1 to 10 days) before cardiorespiratory compromise supervenes.

With the onset of pulmonary edema, patients seek medical attention because of shortness of breath. They may have developed a productive or nonproductive cough by this time. Objective findings include tachypnea, fever, mild hypotension, and often surprisingly few physical signs of pulmonary edema. At this stage there is evidence of arterial desaturation

**FIGURE 68-4** Schema of clinical course of severe hantavirus pulmonary syndrome (HPS). META, metamyelocytes; HCT, hematocrit; AST, aspartate transaminase; LDH, lactate dehydrogenase; PTT, partial thromboplastin time. (Prepared by Li Lien Yang.)

**Table 68-2** Pathogenesis of Typical HFRS from Hantaan Virus Infection and HPS from Sin Nombre Virus Infection

HFRS	HPS
<b>Incubation</b> Typically 2–3 wk (7–42 days)	Typically 1–2 wk (1–4 wk)
<b>Early Signs, Symptoms, and Antibody Response</b> 3–5 days' fever, myalgia, malaise; often gastrointestinal symptoms; flushing, conjunctival injection IgM antibody and immunoblasts already present	3–5 days' fever, myalgia, malaise; often gastrointestinal symptoms IgM antibody and immunoblasts already present
<b>Disease Course</b> DIC, kinin, complement activation; bleeding diathesis Back pain, retroperitoneal leak Hypotension and shock Defervescence Shock lasting 12–48 hr	Abnormal PTT, platelets Dyspnea, hypoxemia, pulmonary edema Hypotension and shock Some continued fever Shock and pulmonary edema worsening up to 24–48 hr
<b>Recovery</b> Oliguric renal failure; problems in circulatory status, bleeding, fluid balance Diuresis 5–10 days later	Pulmonary failure and shock management Resolution of lung lesion and shock in 3–6 days

DIC, disseminated intravascular coagulation; HFRS, hemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome; PTT, partial thromboplastin time.

by oximetry or blood gas analysis. The chest radiograph usually shows subtle (peribronchial edema, Kerley B lines) or marked (alveolar pattern, pleural effusions) signs of increased pulmonary vascular permeability<sup>140</sup>; early on there may be a normal radiograph, a basilar pattern, or asymmetric development of edema.<sup>141</sup>

Several clinical laboratory abnormalities will almost always be present within a day of onset of dyspnea: thrombocytopenia, left shift (the white blood cell count may be normal, but there is often leukocytosis), and atypical lymphocytes.<sup>33</sup> Unfortunately these are not always present to aid in the initial diagnosis. Mildly elevated AST, prolonged partial thromboplastin time (PTT), slightly decreased serum bicarbonate, and increases in serum lactate dehydrogenase (LDH) often occur as well. Severe metabolic acidosis and increased lactate levels above 4 mmol/L are poor prognostic signs.<sup>142</sup> The development of DIC or a clinically significant bleeding diathesis is seen only in a minority of patients.<sup>34,143</sup>

The hospital course is marked by a rapid and progressive increase in hypoxemia. Some patients abruptly have arrest in the emergency ward, and others require intubation within a few hours. About a third of patients are managed successfully with careful monitoring and oxygen administration. Severely ill patients may have copious quantities of endotracheal secretions with protein values exceeding 80% of those of serum and an electrophoretic pattern resembling that of serum.<sup>138,142</sup> Most deaths occur within 48 hours of admission. Patients who are stabilized and survive 2 to 3 days will usually survive, although a few die later with findings of diffuse alveolar damage<sup>34</sup>; it is not known whether this pulmonary finding is secondary to the HPS process or a reflection of lung damage from ventilatory support and secondary bacterial infection.

Although the pulmonary findings dominate the initial presentation of the patient, there are also important independent cardiovascular effects that can be fatal even if hypoxia is properly managed.<sup>142,144</sup> Patients often have low cardiac output, elevated systemic vascular resistance, and a normal or even low pulmonary wedge pressure. Fluid administration and inotropic support may not reverse this picture and the final outcome can be progressive lactic acidosis and fatal shock, often terminating in electromechanical dissociation. Echocardiography in some patients has shown left ventricular contractility to be markedly reduced.

Within a few days most patients will have an improved cardiopulmonary status, and respiratory and circulatory support can be discontinued. In the absence of complications, most patients leave the hospital within 10 to 14 days. No definite sequelae beyond those of intubation and hypoxia have been identified, although emerging studies suggest that there may be prolonged respiratory compromise in some cases.

### Infection with Other Sigmodontine Hantaviruses

Most HPS identified in the United States and Canada has been caused by Sin Nombre virus. Different, but related, viruses have caused HPS in the United States and elsewhere in the Americas. The disease reported with Juitiba virus in Brazil,<sup>145</sup> Laguna Negra virus in Paraguay,<sup>93</sup> Lechiguanas virus in Argentina, and Andes virus in Argentina and Chile<sup>92,146,147</sup> is virtually identical to that of Sin Nombre virus. In other situations there has been a similar clinical picture with variations. A single nonfatal infection with Black Creek Canal

virus in Florida showed typical HPS associated with modest renal failure (creatinine, 4.6 mg/dL) and a markedly elevated serum creatine phosphokinase (CPK).<sup>148</sup> In the southern United States, three cases associated with Bayou virus have been seen and were also associated with renal failure and markedly elevated serum CPK; two patients survived.<sup>149,150</sup> In the northern zone of Argentina near Bolivia, concomitant renal failure also seemed to be commonly found in what is thought to be infection with Oran virus.<sup>92,147</sup> In one Andes virus outbreak in Argentina, flushing of the facial area was noted in some patients. An outbreak caused by Andes virus in Chile had several patients with petechiae and even frank bleeding.<sup>151</sup> Thus, the basic Sin Nombre virus pattern will probably have many variations as the clinical syndromes associated with these other viruses are delineated.

In Paraguay and in Salta province of Argentina, substantial antibody prevalence has been found among healthy persons sampled for surveillance purposes, but it is difficult to interpret these data relative to the virulence of the viruses known to cause HPS in those areas because the hantavirus specificity of the antibodies is unknown.<sup>93,152</sup> The surveys were performed with an immunoglobulin G (IgG) capture enzyme-linked immunosorbent assay (ELISA) that detects antibodies from a wide variety of sigmodontine and arvicoline hantaviruses.<sup>139</sup> Almost all Sin Nombre virus infections are clinically evident based on studies of contacts of index cases during the 1993 epidemic in the southwestern United States,<sup>59</sup> intensive searches for milder disease forms in clinics,<sup>153</sup> and the very low incidence of antibodies found in normal populations in the United States.<sup>154</sup>

### Pathologic Features

Pathologic lesions in both HFRS and HPS are primarily vascular with generalized capillary dilation and edema. Hantaviral antigens are present in abundance within vascular endothelia of patients with fatal HPS and HFRS. In contrast, morphologic changes of the endothelium are uncommon and, when present, consist of prominent and swollen endothelial cells, suggesting that the increased vascular permeability and edema most likely stem from dysfunctional changes in endothelial cells.

In patients with HFRS, large amounts of protein-rich gelatinous retroperitoneal edema fluid is found during the hypotensive stage of the disease. A characteristic triad is congestion and hemorrhagic necrosis of the outer renal medulla, anterior pituitary, and right atrium.<sup>96,112,119,155,156</sup> Microscopically, the most characteristic changes in HFRS are seen in the kidney, with variable degrees of tubular dilation, degeneration, necrosis, interstitial hemorrhage, and mononuclear inflammatory cell infiltrates. These changes are mildest in NE and most severe in Hantaan virus-associated HFRS. An interstitial pneumonitis, similar to that seen in HPS, is seen in some fatal cases.

Typical fatal HPS cases differ from HFRS in that the lesions are primarily confined to the thoracic cavity and are not usually associated with hemorrhage.<sup>33,34,156</sup> Pleural effusions are accompanied by diffuse interstitial and alveolar pulmonary edema. Interstitial pneumonitis is characterized by mononuclear interstitial infiltrate composed of T cells (both CD4+ and CD8+) and activated macrophages. Hyaline membranes are usually scant, and other histopathologic features of diffuse alveolar damage typically are not present. In spite of abundant

pulmonary capillary endothelial viral antigen expression, there are few morphologic lesions in most cases, even at the ultrastructural level. Lymphoid tissue shows an active immune response with variable numbers of immunoblasts present within the red pulp, periarteriolar sheaths of the spleen, and sinuses of lymph nodes. Hantaviral antigens can usually be detected in follicular dendritic cells present within germinal centers.<sup>34</sup>

## **PATHOGENESIS AND IMMUNITY**

Both HFRS and HPS have remarkable similarities in their pathogenesis (see Table 68-2). In both diseases, antibodies are present from their earliest clinical stages<sup>2,139,157,158</sup> and activated T lymphocytes are found in peripheral blood.<sup>33,159</sup> This, of course, suggests an immunopathologic basis for at least part of the disease syndromes.

In the case of HFRS, several clinical findings must be addressed. The fever, increase in vascular permeability, and shock can be explained by the presence of mediators of inflammation released during the immune response to the virus.<sup>160</sup> Elevated serum levels of cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin (IL)-6, IL-10, interferon (IFN)- $\gamma$ , and IFN- $\alpha$  are present,<sup>161,162</sup> and within the kidney endothelial adhesion molecules are increased with the concomitant presence of mononuclear cells expressing TNF- $\alpha$ .<sup>162</sup> Nitric oxide (NO) production is also increased.<sup>163</sup> Bradykinin is one candidate for a major mediator of shock.<sup>113</sup>

The renal failure of HFRS is not simply due to shock and acute tubular necrosis, because of the lack of correlation of these clinical events with the histopathologic findings.<sup>108</sup> It is possible that metabolically vulnerable sections of the medullary nephrons near the cortical border suffer damage when the circulation to the kidney is compromised by intrarenal factors and circulatory instability.<sup>160</sup> Other factors may be involved, such as the intrarenal production of mediators and the infection of renal endothelial and tubular epithelial cells.<sup>32,164,165</sup> The extraordinary hyposthenuria seen during and after the oliguric phase is presumably related to the location of the lesion in the renal tubule. Anterior pituitary necrosis may have a similar pathogenesis involving its portal circulation. The origin of the right atrial necrosis and hemorrhage is not known. Bleeding during the early phases of the disease is probably related to vascular infection, with Hantaan virus triggering a procoagulant state in endothelium that leads to DIC. Later, a uremic coagulopathy is superimposed.

HPS is thought to result primarily from the influx of activated T lymphocytes into the lung with subsequent secretion of mediators and activation of macrophages.<sup>34</sup> Direct measurement of T-cell mediators in the circulation has supported this idea.<sup>165</sup>

One may ask whether HPS is just a variant of acute respiratory distress syndrome (ARDS) or of HFRS. While the finding of bilateral infiltrates and hypoxemia in HPS meets the usual clinical definition of ARDS, the clinical entity of sepsis-associated ARDS differs from HPS in clinical presentation,<sup>141</sup> pathology,<sup>33,34</sup> pathogenesis (typical ARDS damage mediated by polymorphonuclear leukocyte mechanisms), radiology,<sup>140</sup> and the presence of multiorgan dysfunction in ARDS.

Besides pulmonary dysfunction, another factor that may contribute to the severe shock syndrome observed in HPS patients is myocardial dysfunction. In occasional patients

with HPS, extensive amounts of hantaviral antigens can be found in the microvasculature of cardiac tissues, despite little histologic evidence of tissue damage or inflammatory cell infiltrate. However, it is not clear how the magnitude or extent of involvement of cardiac endothelial cells contributes to the pathophysiology of the shock syndrome.

Similar comparisons with HFRS suggest that the pulmonary syndrome caused by Sin Nombre virus infection is a distinct entity. There is massive, selective accumulation of viral antigen in pulmonary endothelial cells, with other capillary beds far less affected and other cell types inconsistently involved. In HFRS, endothelial infection is also disseminated, albeit with some concentration in the kidney.<sup>34,112,156</sup> Although both HPS and HFRS demonstrate activation of mediators that participate in the sepsis syndrome, the patterns of organ involvement between the two diseases and compared with the sepsis syndrome are different (see Table 68-2). Severe HFRS from Hantaan virus infection regularly has early signs of DIC,<sup>111</sup> early activation of kinin pathways,<sup>113</sup> massive retroperitoneal edema,<sup>119</sup> and obvious cutaneous manifestations of increased vascular permeability and vascular instability,<sup>39,108</sup> whereas Sin Nombre virus infection uncommonly shows DIC or hemorrhagic manifestations and has massive intrathoracic vascular "leak" manifested by pulmonary edema and pleural effusions,<sup>36</sup> but signs of systemic vascular leak and dilation are not seen on physical examination.<sup>138</sup>

There is a pulmonary lesion in both HFRS and HPS; careful conventional and CT imaging has demonstrated pulmonary infiltrates or effusions in half of Puumala virus-infected patients as well as decreased diffusion capacity and other pulmonary functions in most patients with relatively mild HFRS, so clearly there is a functional defect in the lung to match the interstitial mononuclear infiltrate seen in postmortem examination of Hantaan virus-infected patients.<sup>166,167</sup> However, when pulmonary edema is seen in HFRS it usually is a consequence of overhydration, although occasionally it may occur early in the disease course, suggesting massive cytokine activation.<sup>168-170</sup> The pathogenesis of pulmonary lesions in HFRS requires more investigation, as does the origin of the renal and hemorrhagic lesions seen in some HPS patients, particularly those infected with sigmodontine hantaviruses other than Sin Nombre virus.

## **Host Factors**

In Puumala infection, the host major histocompatibility complex (MHC) is either protective or predictive of more severe disease, depending on the haplotype.<sup>171</sup> In addition, data for all hantavirus diseases suggest that children suffer less disease than expected.<sup>172</sup> This has not been properly studied or analyzed in terms of infection-disease ratios and risk factors. The only HPS outbreak involving a significant number of children was the epidemic in Chile in which 6 of 28 (21%) patients were less than 16 years of age, compared with only 8 of 176 (4%) of U.S. patients.<sup>151</sup>

## **DIAGNOSIS**

### **Differential Diagnosis of Hemorrhagic Fever with Renal Syndrome**

Any patient with fever, thrombocytopenia, and renal abnormalities should be suspected of having hantavirus disease.

Common diseases entering into the differential diagnosis include leptospirosis, murine or louse-borne typhus, pyelonephritis, malaria, and other hemorrhagic fevers (see Chapter 65). In addition, poststreptococcal glomerulonephritis, blood dyscrasias, glaucoma, and acute abdominal emergencies may be important in the differential diagnosis. Severe cases may resemble fulminant sepsis, and milder cases could be mistaken for influenza, hepatitis A, or streptococcal pharyngitis. The leukemoid reaction occasionally seen may suggest leukemia to the inexperienced clinician, particularly with the appearance of myelocytes and atypical lymphocytes in peripheral blood. Hemoconcentration associated with vascular leak may be mistaken for dehydration in the febrile, vomiting patient; if hypotension is present it may be attributed to the dehydration, and ensuing renal failure may be attributed to the hypotension or the effects of antibiotics given for the presumed bacterial gastroenteritis.

The clinical picture of Puumala virus infection with its milder presentation and lesser abnormalities of blood and renal function can be difficult to recognize if the diagnosis is not considered and sought. The most important consideration, also valid for Hantaan virus infection, is disease mimicking an acute abdominal emergency, which should be distinguished by routine urinalysis and blood examination.

### Differential Diagnosis of Hantavirus Pulmonary Syndrome

Recognition during the prodrome is difficult, but once dyspnea is reported, the finding of thrombocytopenia, left shift (often with leukocytosis and myelocytes), or immunoblasts is common and is helpful. Hypoxemia may be present early, even with a virtually normal chest radiograph.<sup>140</sup> Suspicion of the diagnosis during this phase is critical because of the precipitous fall in oxygenation that may occur over the next few hours. Confusing presentations with abdominal pain and gastrointestinal symptoms may cause misdiagnosis of an acute abdominal emergency. The initial fever and myalgia may lead to consideration of influenza, but the latter typically has cough and coryza among early symptoms, whereas HPS patients rarely have respiratory symptoms until the cardiorespiratory phase. Pneumococcal and other pneumonias can be ruled out because of the symmetric findings of interstitial infiltrates progressing to alveolar pulmonary edema in HPS, although a few cases have had asymmetric findings in the early hours of disease. Misdiagnosis of pneumonia has led to excessive fluid loads associated with antibiotic administration and misinterpretation of the elevated hematocrit as due to dehydration requiring rapid infusion of intravenous fluids.

It should be kept in mind that the flushing, conjunctival injection, and hemorrhagic signs, which are usual in severe or moderate HFRS, have not been seen in North American or in most South American cases until late stages of a minority of severe cases that demonstrate DIC. Renal failure may occur with Bayou, Black Creek Canal, or some South American viruses, but most infections with sigmodontine-derived hantaviruses will have only proteinuria and perhaps mild elevation of creatinine.

### Laboratory Diagnosis

The diagnosis of all known hantavirus diseases is best made by IgM capture ELISA using an infected cell lysate as

antigen and employing an uninfected control for each unknown serum. This test is sensitive, specific, rapid, and inexpensive.<sup>139,157,158,173</sup> Positive results have been obtained with virtually every serum sample from HFRS or HPS patients, including serum drawn during the early febrile phases. The test is cross-reactive and may detect acute hantavirus infections caused by other viruses than the one used to prepare the antigen, both a blessing and a curse depending on the situation. For example, the use of the Sin Nombre virus antigen has detected all known agents of HPS in the Americas.<sup>139,145–149,151,174–176</sup>

Other serologic tests may be employed: Western blots with recombinant New World hantavirus antigens have provided useful diagnostic reagents,<sup>175,177,178</sup> and indirect fluorescent antibody (IFA) tests have classically been used in diagnosis of Hantaan virus infections.<sup>1,177</sup> Any “sandwich” IgM method suffers from the specificity of the IgM conjugate (a serious problem with IFA tests) and from competition between IgG and IgM antibodies as well as rheumatoid factor giving false positives, and any test without a negative antigen control for each serum sample must deal with the inevitable false positives arising from nonspecific “sticky” serum, as well as the possibility of binding to nonviral components of the test antigen preparation.<sup>179</sup> Serologic surveys or tests on convalescent patients may require IgG antibody determinations to assess the history of infection or to identify the infecting serotype. The IgG ELISA provides a sensitive, specific, and practical test for determining seroprevalence. Such antibodies are known to persist at least from the Korean War in the early 1950s until the late 1990s, and seroprevalence in many populations is less than 0.5%, suggesting considerable specificity. In general, when attempting to ascertain the infecting virus, Hantaan virus and Seoul virus are more cross-reactive with one another and the arvicoline and sigmodontine viruses among themselves. The most specific serologic test available is the neutralization test, but even in that assay differences between close phylogenetic relatives are not necessarily large and results can be misleading.<sup>3,89,90,139,180,181</sup> ELISA tests with truncated recombinant antigens<sup>182</sup> and hemagglutination-inhibition tests<sup>79</sup> have shown some utility in distinguishing Hantaan virus and Seoul virus infections, but the best serologic alternative to the technically difficult neutralization test in New World hantavirus infections has been Western blot tests with selected epitopes.<sup>4,175,180</sup> None of these assays has been evaluated against a battery of known sera, and unfortunately such a collection does not exist. The IFA test has been useful in detecting hantavirus disease around the world and is still useful for its cross-reactivity<sup>66,139</sup> but apparently suffers from nonspecific reactions that are more important in interpretation of data in low-incidence populations (T. G. Ksiazek, unpublished observations).<sup>158,183</sup>

The use of RT-PCR has been essential to recent advances in hantavirus research. Because the viruses are difficult to isolate, that approach is inefficient.

Development of sensitive primers to apply to clinical situations and to rodent reservoirs has allowed the definitive identification of the infecting hantavirus in large numbers of patients or suspected reservoirs for the first time.<sup>5,61,184</sup> RT-PCR has no obvious role in acute diagnosis because of the sensitivity of the IgM ELISA, but, combined with sequencing of the amplicon, it is essential when definitive identification of the infecting virus is needed. RNA can be amplified from serum or preferably clotted blood from patients with HPS for at least

10 days of illness and from many HFRS patients.<sup>74,185</sup> It must be borne in mind that cross-contamination between samples either in PCR or virus isolation is easy and that many reported results have been found spurious when sequencing and genetic analysis are applied. Sequencing of viral genomes can be useful in determining the geographical site of infection if sufficient background material is available to allow an assessment of the spectrum of genetic variability and if there is sufficient viral genetic divergence.<sup>5</sup>

Another important diagnostic modality is immunohistochemistry on formalin-fixed, paraffin-embedded tissue. This has been widely used in HPS to confirm diagnoses and to make retrospective assessments of suspicious cases.<sup>34,112,186</sup> RT-PCR can also rescue genetic information from paraffin blocks, but the technique requires careful primer adjustment and shielding against cross-contamination.<sup>187</sup>

## TREATMENT

### Hemorrhagic Fever with Renal Syndrome

As for HPS and other hemorrhagic fevers, rapid hospitalization in a setting of intensive monitoring and careful supportive care is extremely important. The experience in the Korean War strongly suggested that early helicopter evacuation improved the outcome relative to prolonged transport over rough roads. Conversely, long medical evacuation flights of seriously ill patients have been associated with adverse outcomes.<sup>110</sup> Management of shock (see previous discussion), judicious sedation and analgesia, careful evaluation for secondary infections, and appropriately timed dialysis for uremia, hypertension, or electrolyte abnormalities should keep the mortality well below 5% as compared with the 10% seen with careful management without dialysis and the even higher rate in inexperienced hands.

Ribavirin given intravenously within 4 days of onset was shown in one carefully controlled study in China to reduce mortality, bleeding, and the duration of renal failure in a setting in which hemodialysis was not available.<sup>188</sup> Immunosuppression, immunostimulation, and IFN play no role in therapy. In both HFRS and HPS, passive antibody administration has no established role. Indeed, these patients already have an ongoing immune response with neutralizing antibodies present at the onset of disease so that the use of Fab or other blocking strategies might be more plausible than an antiviral antibody strategy. Under these circumstances and in the absence of an animal model of human disease, it is difficult to see how an adequate scientific rationale for such therapy could be established.

The administration of steroids was reported to have a sparing effect in the Korean War experience.<sup>189</sup> In a randomized study of 48 carefully selected, clinically diagnosed HFRS patients with less than 72 hours of symptoms, those treated with 1.1 g oral cortisone over 5 days had a milder course than lactose placebo recipients. The duration of proteinuria and azotemia and the severity of azotemia were judged to be statistically significantly less in steroid-treated patients. Although not statistically different, the steroid group had less fever, were thought to be less "ill," and required less analgesia. No side effects were attributed to steroids; it is interesting that the two deaths in the placebo group were from irreversible

shock, whereas the steroid-treated group tended to have less shock and had no irreversible shock. The three deaths in the steroid group were from gastrointestinal hemorrhage (one case) and bronchopneumonia (two cases). It is not clear that the findings in this small study are relevant to the therapy of hantavirus diseases today, given improvements in the ability to support patients, the potency of corticosteroid dosage, and the possible side effects of steroids.

### Hantavirus Pulmonary Syndrome

Early recognition and admission of the patient are crucial to survival. A small minority of patients has been identified who do not seek medical care and survive, but because of the rapidity of decompensation all patients should have careful monitoring for administration of supplemental oxygen to combat hypoxemia; the majority will require intensive cardiopulmonary support. Mortality at best is about 30% to 40%. When patients first present, hypoxemia should be managed by high concentrations of inspired oxygen through a nonbreathing mask, and the circulation should be supported by modest use of fluids and early administration of inotropic and pressor agents. If possible, a Swan-Ganz catheter should be used for careful monitoring of the circulation, and sufficient fluid should be given to assure adequate filling pressure. Fluids should not be "pushed" without monitoring, and it should not be assumed that patients will respond as those in septic shock with its differing hemodynamic pattern.

There is no known specific therapy for HPS. Ribavirin was used in an open-label study in 1993 and 1994, with no obvious improvement compared with untreated controls, perhaps because of the immunopathologic nature of the disease and the short time available between admission and death (usually only 24 to 48 hours).<sup>190</sup> Ribavirin is now under careful evaluation in a double-blind, placebo-controlled trial. Extracorporeal membrane oxygenator support has resulted in survival of a gravely ill patient expected to die, as has administration of NO.<sup>144</sup> Until a definitive diagnosis is obtained, treatable conditions such as plague, tularemia, or rickettsial diseases, which could be confused with HPS, should stimulate appropriate antibiotic coverage.

In high-risk situations or when dealing with contacts of patients such as in the Andes virus epidemic with person-to-person transmission,<sup>176</sup> the use of convalescent plasma containing neutralizing antibodies could be used early, or the subject could be monitored and treated with intravenous ribavirin at the first sign of fever. Neither of these approaches is of known efficacy, and both have potential side effects so they should be undertaken with careful virologic and clinical monitoring and informed consent, if at all.

## PREVENTION

Reduction of human-rodent contact is the key to prevention. Guidelines generally emphasize the denial of access to dwellings by rodent-proofing, removal of cover for rodents near dwellings, and protection of food sources within homes.<sup>96,191</sup> For example, it has been possible to markedly reduce entry of rodents into rustic cabins in the United States with modifications of only moderate cost.<sup>192</sup> Infestations of rodents should

be eliminated from dwellings by snap-trapping (do not use live traps or glue boards). Simultaneous rodent proofing is important to prevent reinfestation.<sup>193,194</sup> Pretreatment with insecticides is important in areas where plague is endemic.<sup>191</sup>

Handling dead rodents and cleaning rodent nests within buildings is probably dangerous, and gloves should be used to protect skin; the rodent and surrounding detritus should be wetted with a household disinfectant or detergent. Little work has been done on the environmental stability of hantaviruses because of the difficulty in assays and the many possible variables. The viruses are lipid-enveloped and susceptible to common disinfectants and would be lysed by thorough exposure to detergents. In solution they are quite labile at acid pH (<5.0) but are relatively stable when held at neutral pH, particularly if protein is present as a buffer. Small amounts of virus can be detected after several days at 4°C to 22°C. In limited experiments with dried Hantaan virus in buffer, residual infectivity was decreased after rehydration.<sup>195,196</sup> It is likely that excreta exposed to drying and environmental temperature no longer contain infectious virus after 1 to 2 days. Areas inhabited by rodents should be cleaned with a wet mop or after wetting with detergent; in no case should a vacuum cleaner be used. In the particular case of infrequently occupied cabins, the structure should be opened and allowed to ventilate for an hour or more before entering and cleaning. Disturbing the environment within such structures may result in rodent activity and generation of aerosols that are protected from dissipation by breezes and from inactivation by the ultraviolet light of sunshine.<sup>101</sup>

Nosocomial transmission or interpersonal transmission has never even been suspected in HFRS, in spite of the large number of patients and the lack of precautions during early hemodialysis therapy in Korea.<sup>65,66,95</sup> When large antigen accumulations were found in lung tissue of HPS patients,<sup>34</sup> it became particularly important to rule out spread to medical personnel, and no clinical or serologic evidence of such infection was found among 266 exposed health-care workers.<sup>197</sup> It was therefore surprising to find clear epidemiologic, ecological, and molecular genetic evidence of limited interpersonal spread during a small Andes virus epidemic in Patagonia in 1996.<sup>176</sup> The significance of this observation is unknown, but retrospective examination of the U.S. experience failed to find any evidence suggesting nosocomial or person-to-person transmission.<sup>198</sup>

The need to educate at-risk populations about the true risk from rodent exposure is acute in the United States where the disease is rare but the case-fatality rate is high.<sup>143,199</sup> Interestingly, in Europe, where there are many more infected persons, albeit with less mortality, there is almost no public health education. In some occupations and in residents of many areas of Asia and South America, rodent avoidance is not a practical solution, and vaccination is the only practical approach.

Vaccine development for hantaviruses may be particularly difficult given the lack of an animal model for hantavirus diseases and the fact that the diseases are thought to be immunopathologic in origin. Animal models do exist for encephalitis (suckling mice) and for antigen accumulation (hamsters, rabbits, rats, natural hosts) so that passive and active protection experiments can be done. Recent development of a realistic hamster model for HPS<sup>200</sup> should open the

way for accelerated vaccine development.<sup>201</sup> In vitro neutralization of hantaviruses is efficient, and passive antibody transfer of polyclonal and monoclonal neutralizing serums can prevent infection in animal models.<sup>4,202</sup> In the mouse, CD8+ T lymphocytes are also capable of conferring protection.<sup>203</sup> Several types of immunogens have blocked hantavirus infection in these animal systems, including infection with cross-reacting hantaviruses, vaccinia-vectored genes, baculovirus-expressed proteins,<sup>204</sup> inactivated virus preparations,<sup>205</sup> and DNA vaccines.<sup>201</sup> The relatively close genetic relationships among the American hantaviruses,<sup>206</sup> the cross-reaction seen in neutralizing antibodies,<sup>180</sup> cross-reactive T cells,<sup>207</sup> and cross-protective relationships suggest that there might be a basis for a relatively simple vaccine protecting against multiple HPS viruses.

In Asia, Hantaan and Seoul viruses appear to be major health problems, and it may be possible to protect against both viruses with a single vaccine because cross-neutralization, cross-reactive T cells, and cross-protection against infection can be demonstrated in rodent systems.<sup>203</sup> In the Americas, the number of hantaviruses causing disease is large, and the impact of any one of the viruses is relatively small. If cross-protection could be obtained, there would be a place for a vaccine to deal with local epidemics and particularly high-risk situations.

Hantaan and Seoul virus vaccines are being tested in humans with initially promising results, and it is hoped that published efficacy trials in humans will be available to permit evaluation of their place in the prevention of HFRS.<sup>205,208–210</sup>

# Sandfly Fever, Oropouche Fever, and Other Bunyavirus Infections

ROBERT B. TESH

## INTRODUCTION

The family Bunyaviridae includes more than 300 antigenically distinct members, most of which are transmitted by arthropods.<sup>1</sup> At least 41 of these viruses have been associated with human illness in the tropics. Apart from those members that produce serious and sometimes fatal disease (i.e., the hantaviruses, Rift Valley fever virus, and Crimean-Congo hemorrhagic fever virus), most of the remaining human pathogenic tropical bunyaviruses produce nonspecific febrile illnesses. Because of their nonspecific nature and the limited virus diagnostic capabilities in many tropical countries, these infections are often unrecognized or are misdiagnosed as other more common febrile illnesses such as malaria or dengue. This chapter describes some of the more common bunyavirus fevers.

## PHLEBOTOMUS (SANDFLY) FEVER

Historically, phlebotomus fever (PF) has been mainly a disease of military importance, since it typically has caused epidemics when large numbers of nonimmune adults enter an area of endemic virus activity. The disease occurred in troops during the Napoleonic Wars, the Austrian occupation of the Adriatic, the British colonization of India and Pakistan, and the North African and Mediterranean campaigns in World War II.<sup>2,3</sup> The largest reported outbreak of PF occurred in Serbia in 1948, when over 1 million persons were affected. PF outbreaks still occur among tourists vacationing in the Mediterranean region.<sup>4-7</sup>

Many of the PF group of viruses appear to be maintained in their insect vectors by vertical (transovarial) virus transmission.<sup>3</sup> Consequently, virus activity is determined primarily by adult sandfly activity rather than by the immune status of the local human or animal populations. During periods of vector abundance (i.e., summer in subtropical or Mediterranean

climates and the rainy season in drier tropical climates), phlebovirus activity is continuous. In this situation one sees little illness in the native population, most of whom are already immune, but when a group of nonimmune adults enters the area, an epidemic quickly ensues.<sup>2</sup>

Although more than 40 PF virus serotypes have been described,<sup>2</sup> three viruses (Naples, Sicilian, and Toscana) account for most of the recognized PF cases. This is probably because their sandfly vectors (*Phlebotomus papatasi*, *P. perniciosus*, and *P. perfiliewi*) are highly anthropophilic, readily enter houses, and have a wide geographic distribution in the Mediterranean region and central Asia.<sup>3</sup> In contrast, most of the New World phleboviruses and their vectors have a more focal and sylvan distribution; consequently, PF cases in this region are infrequent and occur mainly in persons who enter forested areas for work or recreation.

After an incubation period of 3 to 5 days, PF begins suddenly with fever, severe frontal headache, retroorbital pain, photophobia, malaise, anorexia, nausea, vomiting, and low back pain.<sup>8</sup> The face is often flushed and the conjunctivae are injected, but a true rash is absent. The disease is self-limited, and symptoms usually disappear within 2 to 3 days; however, a general feeling of weakness and depression frequently lasts for a week or more after the illness. A marked leukopenia ( $<4000/\mu\text{L}$ ), consisting of an initial lymphopenia, followed by a protracted neutropenia, also occurs in PF.<sup>8</sup>

Meningitis or meningoencephalitis sometimes occurs with Toscana virus infection. Originally described in central Italy, this infection probably occurs throughout much of the Mediterranean region of Europe. These cases began as classic PF, with a nonspecific febrile illness for 2 to 4 days before the appearance of more serious symptoms, such as nuchal rigidity, positive Kernig's sign, lethargy, and mental confusion.<sup>7</sup> In these cases the hematologic picture is similar to that of classic PF, but the cerebrospinal fluid (CSF) may show increased pressure, pleocytosis (11 to 1400 cells/ $\mu\text{L}$ ), and elevated protein content. The neurologic abnormalities usually resolve in a few days, and patients recover spontaneously in 1 to 2 weeks, although headache may persist.

The recovery of phleboviruses from patients with PF is uncommon, since the viremia associated with this disease is quite transient (24 to 36 hours), and most patients do not seek medical care so early. The one exception is patients with neurologic disease due to Toscana virus infection; virus can sometimes be recovered from the CSF after it has disappeared from the blood.<sup>6</sup> Culture in Vero cells is the isolation system of choice for most phleboviruses.<sup>2</sup>

A number of serologic techniques can be used for the diagnosis of PF, but each has its limitations. The IgM-capture enzyme-linked immunosorbent assay (ELISA)<sup>9</sup> and plaque reduction neutralization test (PRNT)<sup>2,10</sup> are quite specific and sensitive, but one must screen against a variety of phlebovirus serotypes because of their focal and sometimes overlapping distribution. Seroconversion can be demonstrated in paired samples by IgG ELISA and by fluorescent antibody (FA) or hemagglutination-inhibition (HI) tests, but these techniques are not serotype-specific.

Treatment of PF is symptomatic. Except for patients with neurologic symptoms, as in Toscana virus infection, hospitalization is usually unnecessary. The headache associated with PF can be severe, and narcotics are sometimes needed for relief.

PF is a self-limited, nonfatal disease, and recovery is complete. One attack of PF confers lifelong immunity against the infecting virus type but not against heterologous serotypes.<sup>8,10</sup> Thus, second cases of the disease can occur among persons living in regions where more than one phlebovirus is active. There are no vaccines for PF. Control measures are directed against the vector and include household spraying with residual insecticides and the use of insect repellents.<sup>3</sup>

## OROPOUCHE FEVER

Oropouche fever is a midge-borne viral disease that has emerged during the past 40 years as an increasing public health problem in tropical America.<sup>11,12</sup> The causative agent, Oropouche virus, was first isolated from the blood of a febrile forest worker in Trinidad in 1955.<sup>13</sup> Since 1961, about 30 outbreaks of Oropouche virus have been reported from the Amazon regions of Brazil and Peru and from Panama.<sup>12</sup> The number of persons affected has varied with each outbreak, but the two largest recorded epidemics (Belem and Manaus, Brazil, in 1980 and 1981) each involved about 100,000 people.

It is postulated that Oropouche virus is maintained in two distinct cycles: (1) an epidemic urban cycle involving the biting midge *Culicoides paraensis* and possibly *Culex quinquefasciatus* mosquitoes; and (2) a silent maintenance cycle in which forest animals (principally sloths) are the vertebrate hosts, and a yet unidentified arthropod serves as the vector.<sup>11</sup> However, the epidemiology of this disease is still not fully elucidated. It is often confused with dengue and other flulike illnesses, and the true incidence is unknown.<sup>12</sup>

Oropouche fever is characterized by the abrupt onset of fever, chills, severe headache, generalized myalgia, arthralgia, anorexia, weakness, dizziness, and photophobia.<sup>11</sup> Nausea, vomiting, diarrhea, and epigastric pain may also occur. Some Oropouche fever patients exhibit brief meningitic symptoms. Rash is rarely present, but leukopenia is a common feature of this disease. The acute clinical illness usually lasts 2 to 5 days, although a period of asthenia and occasionally dizziness may persist for up to a month. A significant percentage of patients (as high as 60% in some outbreaks) have a recrudescence of their original symptoms within 2 to 10 days after they become afebrile.<sup>11</sup> The recurrent illness associated with Oropouche fever seems to occur more commonly in persons who quickly resume strenuous activities. No virus can be isolated from the patient's serum during the recurrent illness, and detectable humoral antibodies are usually present.

Oropouche virus can often be isolated from the patient's serum during the first 2 to 4 days of the disease. The virus can be isolated in newborn mice, adult hamsters, and a variety of mammalian cell cultures. Demonstration of virus-specific antibody can be demonstrated by ELISA, FA, HI, or the PRNT. Treatment is symptomatic. No fatalities have been reported with Oropouche fever; lifelong immunity follows recovery.

There is no vaccine against Oropouche fever. Given our limited knowledge of the maintenance cycle of Oropouche virus, vector control appears to be the best prevention and control strategy. *C. paraensis* is a daytime biter and, because of its tiny size, readily passes through window screens. Spraying in and around houses with residual insecticides seems to be

the best method of control of adult peridomestic populations of this midge vector. Cleaning up rotting vegetation (banana stalks, decomposing fruit, etc.) around houses also helps to eliminate *C. paraensis* larval breeding sites.

## GROUP C AND GUAMA VIRUS INFECTIONS

Group C and Guama viruses are found throughout the New World tropics and subtropics, including Florida, Central America, and the warmer regions of South America.<sup>14</sup> At least 25 different virus serotypes have been identified. Most of the serotypes have focal distribution which coincides with forest or forest-fringe habitats, usually in low-lying swampy areas. These viruses are maintained in a continuous sylvan cycle involving mosquitoes, mainly *Culex* of the subgenus *Melanoconion*, and small mammals such as rodents and marsupials. Humans are infected when they enter the swampy habitats where these viruses are endemic and are bitten by infected mosquitoes. Cases are usually sporadic, and because they are usually not reported, their true incidence is unknown.

Persons infected by group C and Guama group viruses develop sudden fever (38°C to 40°C), severe headache, vertigo, myalgia, arthralgia, and nausea. The fever lasts 2 to 5 days and is sometimes biphasic. Rash is absent. Patients recover with weakness and anorexia lasting 1 or 2 weeks, but without sequelae.

These viruses can be recovered from patients' serum during the acute febrile phase of the illness. They grow well in a variety of cell cultures and kill newborn mice and hamsters. Antibodies can also be detected in paired acute and convalescent serum by HI, ELISA, FA, and the PRNT. Treatment is symptomatic. The major risk factor is occupation; avoidance of swampy forest habitats or personal protection against mosquito bites is the only prevention.

## BWAMBA, ILESHA, AND TATAGUINE VIRUS INFECTIONS

These three bunyaviruses have been isolated repeatedly from sick persons and mosquitoes in east, central, and west Africa.<sup>15,16</sup> The diseases associated with them are similar: the acute onset of fever, headache, vertigo, severe myalgia, and rash, lasting 4 to 5 days and followed by a week or more of asthenia. No deaths or serious complications have been reported. Most of the mosquito isolations of Bwamba, Ilesha, and Tataguine viruses have been made from *Anopheles* and *Aedes* species.<sup>15</sup> The viruses are thought to be maintained in a mosquito-wild vertebrate cycle, but little other information is available. Given their demonstrated disease potential, wide geographic distribution, and the relatively high antibody rates found in serosurveys among humans in some African countries,<sup>14,15</sup> it seems likely that these agents are of greater health importance to the local populations and to visitors than is currently recognized. But because of the paucity of functioning virus laboratories in Africa and the nonspecific nature of illness associated with them, most of these infections are probably never recognized or reported. Diagnosis can be made by virus isolation from blood during the febrile period or by antibody detection in paired acute and convalescent sera.

## INTRODUCTION

Within the family *Filoviridae* there are two genera, *Marburgvirus* and *Ebolavirus*. The hemorrhagic fevers caused by filoviruses are among the most severe with high mortality rates. Filoviruses are considered emerging/reemerging zoonotic agents whose natural host remains unknown. The viruses are highly pathogenic in human and nonhuman primates, and the frequency of outbreaks and their impact on wildlife has been increasing in recent years. Introduction into the human population can lead to serious epidemics when inadequate sterilization of needles and lack of barrier nursing practices result in nosocomial transmission. Interhuman transmission also appears to occur in African homes by contamination through fomites and droplets. In the laboratory setting, the viruses are highly infectious by small-particle aerosols. The viruses attack endothelial cells, dendritic cells, macrophages, and other cells to produce severe hemorrhagic fever for which there is no established treatment.

## AGENTS

### Taxonomy

The family *Filoviridae* is currently divided into two genera, *Marburgvirus* and *Ebolavirus*.<sup>1</sup> Within the genus *Marburgvirus*, there is a single species *Lake Victoria marburgvirus* that is designated “MARV” and contains six strains with the prototype being strain Musoke. The genus *Ebolavirus* consists of four recognized species: *Ivory Coast ebolavirus* (ICEBOV), *Reston ebolavirus* (REBOV), *Sudan ebolavirus* (SEBOV) and *Zaire ebolavirus* (ZEBOV). The prototype virus for the genus is ZEBOV strain Mayinga.

### Evolution

The phylogeny of filoviruses has been determined using GP gene sequences.<sup>2–5</sup> These studies indicate that the family *Filoviridae* has undergone a great deal of divergence. At the nucleotide level, Ebola and Marburg viruses differ by approximately 55%, and at the amino acid level by up to 67%. This divergence is also manifested in the GP gene organization

(expression strategy), as discussed in the following sections. There is also a significant amount of variation among Ebola viruses, which differ from 37% to 40% at the nucleotide level and 34% to 43% at the amino acid level.<sup>2</sup> This divergence indicates that the ICEBOV, REBOV, SEBOV, and ZEBOV represent distinct clades within the phylogenetic tree and probably are distinct virus species. Despite the marked genetic divergence seen in the family, within each species of Ebola virus there is a remarkable amount of genetic stasis.<sup>2,6,7</sup> This stability may point to a state of extreme fitness within a given ecological niche that has not changed appreciably over the last few decades. It is anticipated that filoviruses will be found to be associated with a particular natural host,<sup>8</sup> and that genetic variation seen in the family reflects adaptations of these viruses to their hosts, perhaps even coevolution of virus and host. The similar replication strategy of the family *Filoviridae* to other members of the order Mononegavirales shows their common evolutionary origin from an ancient progenitor. Phylogenetic analyses of conserved polymerase amino acid sequences clearly separate families from one another, but these comparisons show filoviruses to be more closely related to paramyxoviruses than to rhabdoviruses and that pneumoviruses are more like filoviruses than are other paramyxoviruses.<sup>9</sup>

## Virion Structure

Virions are filamentous but pleomorphic, often occurring as either long filamentous forms (with branching) that can reach 14  $\mu\text{m}$  in length, and shorter forms that appear as U, 6, or circular shapes.<sup>10,11</sup> Electron microscopy studies of MARV and EBOV demonstrate ultrastructural differences between MARV and other filoviruses.<sup>11</sup> All filovirus particles have a uniform diameter of 80 nm, but MARV virions recovered from culture fluids are consistently shorter (795–828 nm) than SEBOV (974–1063 nm), ZEBOV (990–1086 nm), or REBOV (1026–1083 nm) particles. Virions are surrounded by a host cell, plasma membrane–derived lipid envelope studded with surface glycoprotein spikes approximately 7 nm in diameter and spaced 5 nm to 10 nm apart on the envelope.<sup>11</sup> The lipid envelope provides protection for the helical nucleocapsid (50 nm in diameter with an axial space 20 nm in diameter and a helical periodicity of 5 nm). The molecular mass of an average filoviral particle is  $3\text{--}6 \times 10^8$  Da with a density in potassium tartrate of 1.14 g/cm<sup>3</sup>.

## Genome Organization and Replication

The genome of all filoviruses consists of a nonsegmented, single, negative-stranded linear RNA molecule and contributes 1.1% of the total virion mass with a molecular mass of approximately  $4.0 \times 10^6$  Da. The average size of a filoviral genome is 19 kb with MARV being slightly larger than EBOV (MARV 19.1 kb; EBOV 18.9 kb). The complete nucleic acid sequence for three strains of MARV (Popp 1967, Musoke 1980, and M/S.Africa/Johannesburg/1975/Ozolin) and four EBOV strains (ZEBOV Zaire strain 1995, ZEBOV strain Mayinga, REBOV strain Pennsylvania, and REBOV strain Philippines) have been determined.<sup>12–15</sup>

The linear arrangement of the genes is nucleoprotein (NP), virion structural protein (VP) 35, VP40, glycoprotein (GP),

VP30, VP24, and RNA-dependent RNA polymerase gene (L). The seven genes of filoviruses are flanked at their 3' and 5' ends by noncoding sequences containing the signals for replication and encapsidation.<sup>14,16–18</sup> Filoviral genes possess highly conserved motifs for transcriptional start (3'-CUNCNUNUAAUU-5') and transcriptional stop (3'-UAAUUCUUUUU-5') signals.<sup>19</sup> Intergenic regions of variable length may exist between adjacent genes; however, some genes are known to overlap. This phenomenon is particularly evident within the genus *Ebolavirus* with three overlaps reported for ZEBOV, SEBOV, and ICEBOV and two overlaps for REBOV. When overlaps occur, their length is limited to five highly conserved nucleotides within the transcriptional signals (3'-UAAUU-5').<sup>12–15</sup>

The extragenic sequences at the extreme 3' (leader) and 5' (trailer) ends of the genome of filoviruses are conserved and show a high degree of complementarity. As with other nonsegmented negative-strand RNA viruses, these ends have important roles as promoters in the transcription and replication of virus RNA. The genes between these promoters are delineated by conserved transcriptional signals, beginning with a start site at the 3' genome end and terminating with a transcriptional stop (polyadenylation) site. Termination of transcription occurs at a series of five or six Us where stuttering (repeated copying) by the polymerase results in the addition of long poly(A) tails to the transcripts.

In addition to differences in transcriptional signals, there are other characteristics that distinguish filovirus genomes from those of other members of the order. One such trait is that filovirus genes tend to possess long noncoding regions at their 3' or 5' end or at both ends, which contribute to the increased length of the genome and may influence expression levels through messenger RNA (mRNA) stability. Analysis of the 5' ends of filovirus mRNAs shows a potential for the formation of stable stem-loop structures, which might also influence stability and could theoretically confer an increased capacity to bind ribosomes.<sup>13</sup> Although Marburg and Ebola viruses are similar in their genetics, these two groups of viruses are distinct from one another in several ways.

While members of both *Ebolavirus* and *Marburgvirus* produce GP<sub>1,2</sub> as the surface glycoprotein, the strategy they employ to do so differs. Members of the genus *Marburgvirus* produce their glycoprotein spike through authentic transcription of the viral RNA. The mechanism used for EBOV, however, is more complex and involves transcriptional editing by the RNA-dependent RNA polymerase. The editing event occurs approximately in the middle of the glycoprotein gene at a stretch of seven consecutive adenosine residues (plus sense). On editing, an additional nontemplate adenosine is inserted, and this causes a shift in the reading frame thereby avoiding a translational stop codon that would be present in exact copies of the viral template. It has been estimated that 20% of all mRNA transcripts from the glycoprotein gene encode the full-length GP<sub>1,2</sub>.<sup>2</sup> The remaining unedited transcripts encode a precursor protein known as pre-sGP, making it the primary product of the glycoprotein gene. Transcriptional editing has been described for certain paramyxoviruses, where insertion of extra nucleotides during P gene transcription allows the expression of additional proteins; however, the editing of Ebola virus gene transcripts is so far the only example of a structural virus GP that is expressed through this mechanism.

## Virus Proteins

Filoviruses produce seven structural proteins from the seven genes encoded by the genome. Four of these seven proteins are associated with the genomic RNA to form the ribonucleoprotein complex (RNP): nucleoprotein (NP), VP30, VP35, and L. Whereas NP, L, and VP35 are functionally conserved within the order *Mononegavirales*, VP30 is thought to represent a filovirus-specific nucleocapsid protein<sup>20</sup> that functions as a minor phosphoprotein of virions. The genomic position of VP35, when compared to paramyxoviruses and rhabdoviruses, has led to the hypothesis that it functions as a phosphoprotein and is involved in transcription and replication.<sup>16,21,22</sup> Additionally, this protein has recently been identified as a type 1 interferon (IFN) antagonist.<sup>23</sup> VP35 blocks double-stranded RNA- and virus-mediated induction of an IFN-stimulated response element reporter gene and blocks double-stranded RNA- and virus-mediated induction of the IFN-beta promoter.<sup>23</sup> The ability of VP35 to inhibit this virus-induced transcription correlates with its ability to block activation of IRF-3, a cellular transcription factor of central importance in initiating the host cell IFN response.<sup>24</sup>

The remaining three structural proteins are all associated with the lipid envelope. The glycoprotein, GP<sub>1,2</sub> is the major surface spike protein and VP40 is the major matrix protein, while VP24 is believed to be a minor matrix protein also involved in the budding process.<sup>25,26</sup> In addition to the structural proteins, a nonstructural soluble precursor protein, pre-sGP, is produced and subsequently proteolytically cleaved into sGP and delta (Δ) peptide.<sup>27,28</sup>

VP40 is a membrane-associated protein, possesses a slightly hydrophobic profile, and is the most abundant viral antigen associated with virions.<sup>12,13</sup> The function of VP40 had been assumed to be as a matrix protein, and more recent studies have shown that expression of VP40 induces filamentous particle formation nearly identical to wildtype virus and, when coexpressed with the surface glycoprotein, spikes are present on the surface of particles, thereby suggesting an interaction of these proteins in morphogenesis.<sup>29,30</sup> Like VP40, VP24 is localized to the viral membrane; however, unlike VP40 it could not be completely removed from the RNP complex under isotonic conditions. Further studies have shown a specific biochemical interaction among VP24, NP, and VP35.<sup>31</sup> VP24 is believed to be a minor matrix protein that links the membrane-bound proteins (VP40 and/or GP<sub>1,2</sub>) with the RNP, perhaps through interaction with VP35 and NP. VP24 may play a role in virus assembly and budding, a conclusion partially based on evidence that it strongly associates with lipid membranes.<sup>25</sup> In addition to a role in viral budding, VP24 is speculated to play a role in species adaption.<sup>32</sup> Specifically, VP24 appears to be a "hot spot" for mutations leading to amino acid changes when EBOV is serially passaged and adapted to cause lethal infection in guinea pigs.<sup>32</sup>

Synthesis of GP<sub>1,2</sub> involves processing by the proprotein convertase furin, a subtilisin/kexin-like convertase localized in the trans-Golgi, at a polybasic cleavage site, and the mature protein consists of the amino-terminal fragment GP<sub>1</sub> (140 kDa; EBOV) and the carboxy-terminal fragment GP<sub>2</sub> (26 kDa; EBOV) that are linked by a disulfide bond.<sup>33,34</sup> GP<sub>1,2</sub> is heavily glycosylated with approximately 50% of its molecular mass attributed to N- and O-glycans.<sup>35,36</sup> Once fully

processed, the mature protein is present as trimeric heterodimers on the surface of particles, and it is speculated that trimerization is mediated through the GP<sub>2</sub> component of the protein.<sup>37</sup> This hypothesis is supported by structural analysis of the crystallized GP<sub>2</sub> portion in comparison to HIV-1 gp41, influenza hemagglutinin, and the fusion protein of paramyxoviruses.<sup>38–40</sup> It has been hypothesized that a coiled-coil region of GP<sub>2</sub> interacts with another region of GP<sub>2</sub> that is identified as a putative fusion domain based on the similarity of its topological position to that of the retroviral transmembrane domain.<sup>41,42</sup>

The major precursor protein of the glycoprotein gene (pre-sGP) is glycosylated and cleaved at the multibasic amino acid motif RVR<sub>R</sub> at positions 321 to 324 of the open reading frame.<sup>27,28</sup> The larger cleavage product is sGP, a 50-kDa protein that is efficiently released as a homodimer.<sup>28</sup> In addition to being observed *in vitro*, it is detected in the blood of EBOV-infected patients.<sup>2,6</sup> The dimerization of sGP is due to an intermolecular disulfide linkage between cysteine residues at positions 53 and 306. Additionally, formic acid hydrolysis of sGP demonstrates that sGP dimers consist of monomers in

antiparallel orientation.<sup>28</sup> It is important to note that while sGP and GP<sub>1,2</sub> share the 295 N-terminal residues, they are structurally distinct. sGP differs from GP<sub>1,2</sub> in its 69 carboxy-terminal residues; however, only 29 of these amino acids are specific for sGP.<sup>2,43</sup> The remaining 40 amino acids are specific for the smaller cleavage product of pre-sGP that has been designated  $\Delta$  peptide.<sup>27</sup> The role of sGP in pathogenesis remains unclear; however, sGP may bind to neutrophils through CD16b, the neutrophil-specific form of the Fc gamma receptor III,<sup>44</sup> although this point has been challenged.<sup>45,46</sup>

## EPIDEMIOLOGY

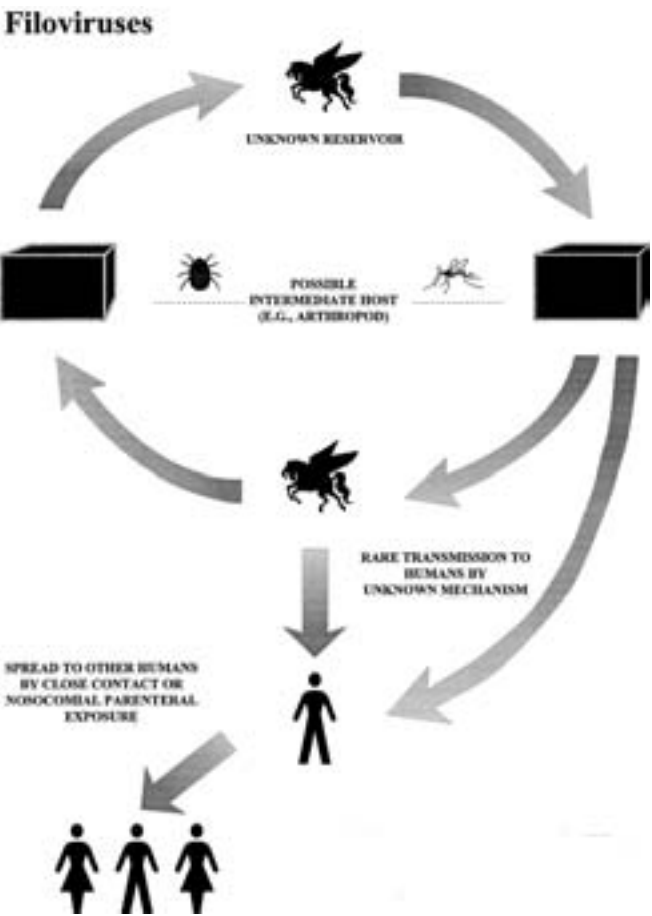

The geographic range of the filoviruses is best based on actual virus isolates; most serosurveys have used the fluorescent antibody (FA) test, which is not reliable for Ebola antibodies. Zaire, Sudan, and Côte d'Ivoire species of Ebola virus are from the African tropical forest or nearby savanna and occasionally emerge during the rainy season (Table 70-1; Fig. 70-1). The Reston Ebola species has only been obtained from a single

**Table 70-1 Human Infections with Ebola Virus Subtypes Zaire, Sudan, and Côte d'Ivoire**

Subtype	Year	Location	Cases (% Mortality)	Circumstances of Human Infection
Zaire	1976	Zaire	318 (88%)	Equateur province. Spread occurred by close contact and by use of contaminated needles and syringes in hospitals and clinics.
	1977	Zaire	1 (100%)	Tandala. Single case diagnosed in missionary hospital.
	1994	Gabon	44 (63%)	Minkebe, Makokou area. Outbreak in gold-mining camps, in deep rain forest, initially thought to be yellow fever; identified retrospectively in 1995.
	1995	Zaire	317 (78%)	Epidemic in Kikwit. Traced to index case who worked in the forest adjoining the city. The epidemic spread through families and hospitals.
	1996	Gabon	37 (57%)	Mayibout area. Chimpanzee found dead in the forest was butchered and eaten; 19 primary cases occurred in those exposed to uncooked meat. Secondary cases occurred in family members. Patients treated in hospital with barrier nursing did not result in nosocomial infection.
	1996	Gabon	60 (75%)	Booué area, with transport of patients to Libreville. Index case was a hunter who lived in a forest camp. Community spread occurred mostly by close contact with patients.
	1996	South Africa	2 (50%)	Physician left Gabon for Johannesburg, South Africa, after having treated Ebola virus–infected patients; he was hospitalized and a nurse was infected and died.
Sudan	1976	Sudan	284 (53%)	Nzara, Maridi, and surrounding area. Spread was thought to be mainly by close contact. Nosocomial transmission and infection of medical care personnel were prominent.
	1976	England	1 (0%)	Laboratory infection by needlestick.
	1979	Sudan	34 (65%)	Nzara. Recurrent outbreak at the same site as the 1976 Sudan epidemic.
Côte d'Ivoire	1994	Côte d'Ivoire	1 (0%)	Ethologist became ill after performing field autopsy on chimpanzee in the Tai forest; repatriated to Switzerland, recovered. The troop of chimpanzees had suffered undiagnosed fatal disease in 1992 and 1994.
	1995	Liberia, Côte d'Ivoire	1 (0%)	Liberian refugee hospitalized and recovered; serologic diagnosis only (IgM, IgG ELISA antibodies).

ELISA, enzyme-linked immunosorbent assay.

**FIGURE 70-1** Transmission cycle of filoviruses. The viruses are maintained in nature by an unknown mechanism. It is most likely that there is a vertebrate reservoir, and it is possible that there might be an arthropod or other intermediate host indicated by a black box. Once the virus is introduced into humans, it is spread by close contact, particularly in the hospital setting. Epidemics have all died out with the institution of quarantine and barrier nursing.

export facility in the Philippines<sup>47,48</sup> (Table 70-2). Because of the uncertainty of where the virus(es) in that facility originated one cannot be dogmatic about the true source of the Reston species. It seems likely that it is an Asian filovirus, perhaps even derived from infected macaques captured in the forests of the Philippines, but because it may alternatively represent a single introduction and subsequent circulation in the export facility, doubt remains as to its ultimate origin. Marburg virus

has apparently been obtained in forested and derived areas of Kenya, Uganda, Democratic Republic of Congo, and Zimbabwe, but the epidemiologic information does not permit clear definition of the exact sites (Table 70-3; Fig. 70-2).

**Ecology**

The natural host and maintenance strategy for any filovirus are unknown; this is a unique situation for any of the known virus families that contain human pathogens. In fact, only modest efforts have been expended on the search for such hosts by the usual standards for other zoonotic human pathogens in the tropical forest, so the lack of understanding may not be so mysterious, but it is still a major deficit in trying to understand and predict filovirus transmission.<sup>48–50</sup> It has been argued that the virologic properties of Ebola virus may favor chronic infection of a mammalian reservoir, and indeed it has been possible to infect bats with modest virus persistence in the laboratory.<sup>51</sup> Laboratory infections of arthropods, reptiles, and plants, as well as cells derived from arthropods and reptiles, have usually failed but, of course, the correct species' cells may not have been chosen.<sup>52</sup> Until field isolations are obtained and those findings backed up by additional field and laboratory studies, any speculation is just that.<sup>8</sup>

**Transmission**

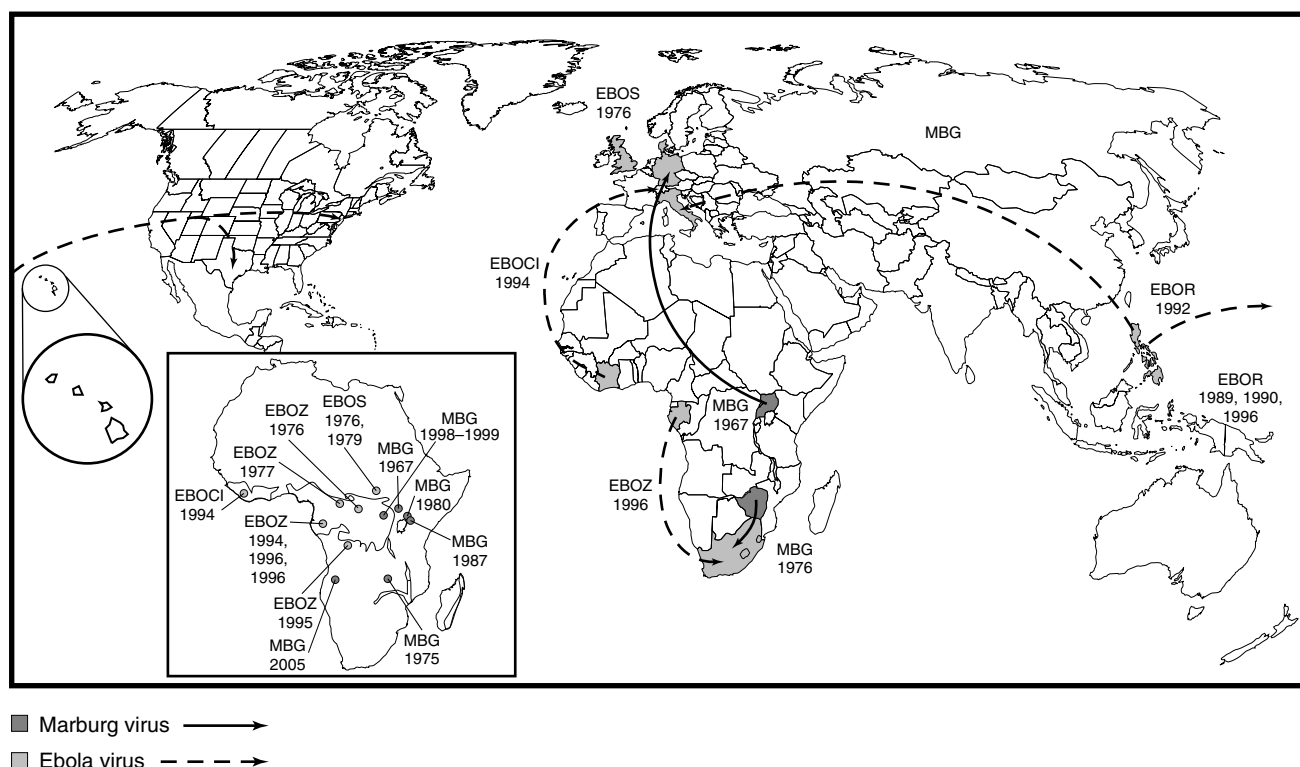

Human infection of the index case has always occurred in rural areas of Africa or through contact with infected nonhuman primates. No common event has been identified among human index cases although proximity to bats (common enough in the tropics when looked for), local travel, and a painful “bite” (a single Marburg case<sup>48</sup>) are often mentioned. The most recent outbreaks in Durba/Watsa (Democratic Republic of Congo) occurred in and/or around a subterranean gold mine where the reservoir(s) seem to be localized. Subsequent spread proceeds readily, particularly to those who care for the patient and are in close contact with body secretions and blood or to those who prepare the body for burial.<sup>53–55</sup> There have been secondary cases among mourners who only touched the body or physicians who only placed hands on sick patients, but these are the minority. There has been no evidence for aerosol transmission between humans although it would be difficult to absolutely exclude any small component of airborne spread.<sup>56</sup> The real engine that drives large Ebola outbreaks is the underfunded African hospital that reuses disposable needles and syringes without sterilization and cares

**Table 70-2** Infections with Ebola Virus, Reston Subtype

Year	Location	Cases (% Mortality)	Circumstances of Infection
1989–1990	United States	4 (0%)	Introduction of virus into quarantine facilities in Virginia and Texas from a single export facility in the Philippines; four acute human infections documented without clinical symptoms
1992	Italy	0 (0%)	Introduction of virus into quarantine facilities in Siena from same export facility
1996	United States	0 (0%)	Introduction of virus into quarantine facility in Texas from same export facility
1996	Philippines	0 (0%)	Studies in implicated export facility once again fail to reveal source of the virus

**Table 70-3** Marburg Virus Human Infections

Year	Location	Cases (% Mortality)	Circumstances of Human Infection
1967	Germany and Yugoslavia	31 (23%)	Imported monkeys from Uganda infected humans through contact with the monkeys or primary kidney cell cultures; there were six secondary cases and no tertiary cases
1975	Zimbabwe and South Africa	3 (33%)	A traveler infected in Zimbabwe died in Johannesburg, South Africa; secondary cases occurred in a companion and a nurse infected while providing patient care
1980	Kenya	2 (50%)	Index case infected in western Kenya and died in Nairobi; a physician was secondarily infected and survived
1987	Kenya	1 (100%)	Expatriate traveling in western Kenya
1990	Russia	1 (0%)	Laboratory infection
1998–2000	Democratic Republic of the Congo	Unknown, but estimated 60/73 (83%)	Repeated introductions of multiple clades of viruses and subsequent interhuman spreads
2005	Angola	277/308 (90%)	Apparently, a single introduction resulted in nosocomial and close contact infection. Epidemic still underway as of May 2005. High case fatality may reflect incomplete ascertainment of nonfatal cases, route of infection, or other variables.

for patients without barrier nursing precautions. Nosocomial spread combined with intrafamilial infection has led to epidemics of several hundred cases in Sudan, Zaire (Democratic Republic of the Congo), and Uganda (see Table 70-1).

The opportunity to formally study cases during the 1995 Zaire epidemic provided important data.<sup>55,57</sup> General patterns of infection resembled former outbreaks, with medical personnel providing almost one-third of the cases. Family members usually were infected in a setting of direct physical contact with the patient and particularly the patient's body fluids. The overall risk for family members caring for patients was increased fivefold compared with others sharing the same cooking fire. Generally, contact during the early phases of illness carried a low risk with most secondary cases attributable to contact during the later stages of disease and particularly in the hospital. This correlates with virologic findings in experimental infections of nonhuman primates.<sup>58</sup> Interestingly, touching the cadaver was an important independent risk factor,<sup>55</sup> which may be correlated with the finding of Ebola antigen and virions in skin biopsies and surrounding skin appendages.<sup>59</sup> A few patients from the 1995 outbreak had no identifiable risk factor such as close contact with a patient or an injection.<sup>56</sup>

The exact route of infection and infecting dose are unknown. Nonhuman primates are readily infected by small quantities of injected virus, by low doses of infectious aerosols,<sup>60</sup> and by placing virus suspensions on the conjunctiva.<sup>61</sup> In Zaire in 1976, 85 patients had an injection history, and all of these patients died compared with 89% of the 149 thought to have been infected by contact with other patients.

All Ebola virus epidemics have stopped, perhaps because of the relatively low transmissibility of the virus once medical care facilities no longer function as sources of virus. The process is aided by the quarantine practiced by local people once the transmissibility and lethality of the disease are recognized.<sup>53,54</sup> In 1995, the only transmission outside the city of Kikwit, Democratic Republic of Congo, occurred in a nearby town with a hospital; villages without medical facilities often strictly confined patients to their houses, and the single case in Kinshasa was managed with barrier nursing without incident, as occurred in 1976.<sup>57,62</sup> The institution of barrier nursing in the hospital in Kikwit clearly stopped transmission to staff while patients continued to be cared for in the medical facility<sup>57</sup>; the rehabilitation of the hospital with use of effective barrier nursing may have been particularly useful in controlling virus spread because of the setting in a large African town with poor communications and the stigmatization of patients and their families leading to concealing cases.

The adaptation of virus to interhuman spread has been suggested as leading to the possibility of more efficient transmission<sup>63</sup> or to the virus becoming attenuated.<sup>64</sup> In fact, the secondary transmission rates in families have generally been 3% to 16% with no change or a small decrease in case-fatality rates over time.<sup>53,55,65,66</sup>

Epidemiology among captive cynomolgus macaques has been studied with the Reston virus species. Extensive spread is associated with reuse of needles and syringes and multidose vials for medications and tuberculin testing. Monkeys housed in groups with an infected monkey are also at high risk. Spread within quarantine facilities in the United States has not been easily controlled. Even with individual cages, use of sterile injection equipment, and precautions by caretakers,

one infected monkey in a room has usually led to the eventual infection of virtually all others, with more than 80% dying. In quarantine facilities in the United States during the introductions in 1989 and 1990, there was spread between rooms sharing common ventilation. It was believed that this movement of virus, the explosive nature of the outbreak in most rooms, the respiratory signs in infected monkeys, and the high titer of virus in secretions argued for some component of airborne spread, but there was no proof of this.<sup>67</sup> Airborne spread has been suggested in episodes with Marburg and Ebola virus in laboratory settings.<sup>60,68,69</sup> Certainly, both viruses have sufficient aerosol stability, as well as the requirement of only about one plaque-forming unit retained in the lungs to kill a monkey.<sup>70-73</sup>

Control of monkey filovirus infections in the United States and Europe has been achieved by quarantine of imported animals.<sup>74,75</sup> Animals that die during quarantine are tested for the presence of filoviruses, usually by the antigen detection enzyme-linked immunosorbent assay (ELISA).<sup>76</sup> Use of antibody tests to detect infection has not been needed because of the high mortality among infected monkeys. During the 1989 and 1990 Reston episodes, numerous confusing titer changes and false positive immunofluorescent antibody (IFA) test results were obtained in humans and monkeys.<sup>77</sup> Thus, if antibody testing is needed to rule out transmission after a member of the cohort is shown to be infected, the ELISA should be employed.<sup>78</sup>

Wild chimpanzees apparently are susceptible to Ebola virus and provide additional epidemiologic data. One animal necropsied in the Tai Forest in Côte d'Ivoire during a die-off was shown to be infected by immunohistochemistry and by infection of the ethologist (only isolation of the Côte d'Ivoire species of Ebola virus) who performed the autopsy.<sup>79</sup> Chimpanzee deaths during the presumed epizootic were particularly prominent among those hunting red Colobus monkeys for meat consumption and contacts of sick monkeys, possibly providing a helpful clue in the search for the reservoir.<sup>80</sup>

Since 1994, in central Africa, Gabon, and Republic of Congo, multiple outbreaks occurred resulting in several hundred human cases originating in devastating epizootics in nonhuman primates (chimpanzees and gorillas).<sup>81</sup> Epidemiological observations, confirmed by molecular results, showed evidence of multiple outbreaks occurring simultaneously in human and nonhuman populations involving emergence of multiple strains of Ebola virus.<sup>82</sup> The patterns of virus transmission between animals or within family groups have not been studied, but survey of known populations showed dramatic declines in gorilla and chimpanzee numbers.<sup>83</sup>

The largest outbreak on record of Ebola hemorrhagic fever (EHF) occurred in Uganda from August 2000 to January 2001. The outbreak was centered in the Gulu district of northern Uganda (393 presumptive cases), with secondary transmission to other districts, Mbarara (5 presumptive cases) and Masindi (27 presumptive cases).<sup>84</sup> Laboratory confirmation was established for 218 of the presumptive cases. There were 29 infected health-care workers. Sequence and epidemiological data were consistent with the outbreak having originated from a single introduction in the human population.<sup>85</sup>

Between November 1998 and May 1999, the largest recorded Marburg epidemic occurred in Durba and Watsa (Democratic Republic of Congo) with a total of 73 cases

(8 laboratory-confirmed and 65 suspected cases retrospectively identified). Follow-up surveillance has subsequently identified a total of 154 probable or confirmed cases through December 2000.<sup>86</sup> During this outbreak, all the patients were either working in a gold mine or were taking care of a sick patient who worked in the same gold mine. Ecological investigation concentrated on the search for a reservoir in and around the mine, but was not successful (Swanepoel and colleagues, unpublished data, 2000). Data from previous Marburg hemorrhagic fever (HF) outbreaks have suggested a single introduction of virus into the human population with subsequent human-to-human transmission during each outbreak. One virus genetic lineage is present in any given outbreak, and no virus genetic variation has been detected during human-to-human virus transmission. Human-to-human virus transmission was seen but not as commonly as in Ebola outbreaks. In this last outbreak, genetic analysis of virus RNA obtained either directly from clinical samples or from virus isolates revealed a high degree of nucleotide diversity (up to 16%) and several distinct virus lineages associated with different human infections. The data indicate that Marburg virus was introduced several times into the human population in the Durba area.<sup>87</sup>

## DISEASE

### Clinical Manifestations

Filovirus infection often results in fulminant hemorrhagic disease in humans and nonhuman primates.<sup>88</sup> Indeed, among all viral hemorrhagic fevers (VHFs), those caused by filoviruses are regarded as the most severe and are typically associated with hemorrhagic manifestations, coagulation disorders, generalized shock, and hepatic involvement.<sup>89,90</sup> Close observations during human cases of filovirus HF have generally been incomplete because of logistics and danger to the health-care worker.<sup>10</sup> The incubation period for filovirus HF is approximately 4 to 10 days (range, 3–19) and is followed by abrupt onset of nonspecific symptoms including fever, chills, malaise, and myalgia. As disease progresses, more severe and multi-system symptoms are noted, such as gastrointestinal (anorexia, nausea, vomiting, abdominal pain, diarrhea), respiratory (chest pain, shortness of breath, cough), vascular (conjunctival injection, postural hypotension, edema), and neurologic (headache, confusion, coma) manifestations.<sup>10</sup> Hemorrhage was usual in the 1976 Ebola epidemics, but was reported in fewer than half of patients in the 1995 Kikwit outbreak and even fewer in Gulu. Maculopapular rash usually appears around day five. Death is usually associated with fulminant shock, which is characterized by fluid distribution problems (increased permeability), hypotension, coagulation disorders, and widespread focal tissue destruction.<sup>91</sup> A humoral antibody response in survivors is observed typically between days 7 and 11, which also marks a turning point to either death or an improvement in health.<sup>92,93</sup> The small percentage of individuals that do not succumb to disease can expect a prolonged period of convalescence with varying degrees of sequelae including arthralgia, uveitis, psychosocial disturbances, and orchitis.<sup>93</sup>

The different viruses may well have somewhat different clinical syndromes, but there have been few opportunities for close

observation of the diseases under good conditions. The mortality from the Ebola Zaire species is high (60% to 90%), the Sudan species somewhat lower (50% to 60%), and Marburg virus probably comparable to Ebola Sudan. The single observed Côte d'Ivoire infection was severely ill but survived, as did a second case diagnosed by serology.<sup>10,53,54,64,67,94–96</sup> The four Reston species infections observed in Reston, Virginia, had no symptoms. One patient serially bled yielded a serum virus isolate, but titers were barely detectable (P.E. Rollin and associates, unpublished observations, 1990). The Reston species clearly has less pathogenicity for humans based on these four carefully observed infections, but that is a small database for sweeping conclusions. Because of the vagaries of the IFA test, it is difficult to be sure of the case-infection ratios in outbreaks, but in both the 1976<sup>54</sup> and 1995<sup>57</sup> Zaire species epidemics, there was no evidence of mild or subclinical disease in patients or family contacts.

### Pathology

Of all the viral hemorrhagic fevers (see Chapter 65), filoviruses have the highest case-fatality rates and cause the most widespread destructive tissue lesions.<sup>59,68,97–102</sup> In fatal Marburg and Ebola cases, hemorrhagic manifestations are usually striking with widespread petechiae and ecchymoses involving skin, mucous membranes, and internal organs; extensive visceral effusions are also present. The histopathologic changes are similar in Marburg virus and Ebola virus infections, and somewhat resemble those seen in other HFs. However, careful study of histopathologic lesions and finding of characteristic viral inclusions in the liver may suggest a specific diagnosis.<sup>10,97</sup>

Focal necrosis is seen in many organs and is maximal in liver, spleen, kidney, and gonads. Electron microscopic, immunohistochemical, and in situ hybridization studies show strong association of parenchymal necrosis in organs and the presence of abundant viral particles, antigens, and nucleic acids<sup>98,99</sup> (Figs. 70-3 and 70-4). Filovirus antigens and particles can also be found in abundance within and in association with, occasionally necrotic, endothelial cells throughout the body. Little or no inflammatory response is seen in association with necrotic areas. Thus, the necrosis appears to be related to both the cytopathic effect of the virus and ischemia. Characteristic histopathologic features are seen in the liver, with widespread hepatocellular necrosis, Councilman bodies, microvesicular fatty change, and Kupffer cell hyperplasia. Filovirus inclusions are seen within the cytoplasm of hepatocytes (see Fig. 70-4A). They are usually numerous in Ebola infections and are eosinophilic, oval or filamentous and ultrastructurally are seen to consist of aggregates of viral nucleocapsids (see Fig. 70-4B). Spleen and lymph nodes show extensive follicular necrosis and necrotic debris. The lungs show interstitial edema and are usually hemorrhagic with features of diffuse alveolar damage. Myocardial edema and focal necrosis are seen but are not associated with any appreciable inflammatory infiltrates.

### PATHOGENESIS AND IMMUNITY

The pathology of EBOV infections has been examined extensively from tissues obtained during human outbreaks

**FIGURE 70-3** Ebola virus antigen-positive cells in lung and liver of an Ebola patient as determined by immunohistochemistry. *A*, Lung showing fibroblast and endothelial cell infection (*arrowhead*) as well as involvement of several alveolar macrophages. *B*, Heavy viral burden and necrosis can be seen in this section of liver immunostained for Ebola virus antigens. Viral antigens are in hepatocytes and Kupffer cells, many of which are necrotic (*arrowhead*). (Immunoalkaline phosphatase staining, naphthol-fast red substrate with light hematoxylin counterstain; *A*,  $\times 158$ ; *B*,  $\times 250$ .)

**FIGURE 70-4** Liver in Ebola virus infection. *A*, Photomicrograph of liver showing hepatocellular necrosis and numerous, eosinophilic, crescent-shaped, intracytoplasmic viral inclusions typical of Ebola virus infection (*arrowhead*). (Hematoxylin and eosin,  $\times 158$ .) *B*, Thin-section electron micrograph of same liver demonstrating that inclusions (*arrows*) are composed of aggregates of viral nucleocapsid. ( $\times 7,000$ .)

in addition to studies using susceptible animal models (mice, guinea pigs, and nonhuman primates). The high containment setting necessary to study filoviruses, along with certain inconsistencies between animal models and human infection, have proven to be challenges in the understanding of filovirus pathogenesis. One aspect concerning animal models that should be kept in mind is that they do not always adequately reproduce EHF; specifically, there are differences in hemorrhagic manifestations, coagulopathy, and bystander apoptosis. Despite these challenges, recent studies have shed significant light on the current model of pathogenesis.

The primary mechanism for human filoviral infection is close contact with skin and secretory products from infected individuals. Virus is believed to enter via small skin lesions and mucous membranes from which it can acquire direct access to the vascular system or indirect access through the lymphatic system.<sup>88</sup> Monocytes/macrophages and dendritic cells (DC) are primary sites of viral replication.<sup>97,103–105</sup> Cells of the mononuclear phagocytic system (MPS) located in multiple organs including the liver (Kupffer cells), spleen, lymph nodes, lung (alveolar macrophages), serous cavities (pleural and peritoneal macrophages) and nervous system (microglia) are infected; however, the lymph nodes, liver, and spleen are the organs consistently preferred for filovirus replication.<sup>89</sup> Organ tropism may be enhanced by direct access of particles to sessile cells of the MPS without penetration of cellular or tissue barriers.<sup>106</sup> Subsequent to infection and replication in macrophages, viral particles gain secondary access to lymph nodes and then ultimately the vascular system, which initiates a state of viremia.<sup>88</sup> In addition to tissues from fatal human cases and in vitro studies, a serial sacrifice experiment of EHF in cynomolgus monkeys has given a tremendous amount of data regarding the progression of disease in the animal model that most closely resembles human infection.<sup>103,107</sup> Virus was shown to spread from initial infection sites by monocytes and dendritic cells to regional lymph nodes, most probably via lymphatics, and to liver and spleen via blood. Virus was then shown to infect tissue macrophages, DC, and fibroblastic reticular cells (FRC).<sup>103</sup> Monocytes/macrophages have been shown experimentally to be early and sustained targets of EBOV in both guinea pigs and moribund monkeys.<sup>61,104,108,109</sup> The recent study in cynomolgus monkeys confirmed these observations with viral RNA detected in lymphoid monocytes/macrophages as early as two days postinfection.<sup>103</sup> The interaction between filoviruses and DC may be critical for the outcomes of EBOV infections. The lymphoid hypoplasia and lack of a detectable immune response in fatal infections could be explained by the early infection of dendritic cells, their increased expression of the TNF-related apoptosis-inducing ligand TRAIL and bystander apoptosis of lymphocytes, the partial suppression MHC class II in EBOV-infected immature dendritic cells,<sup>110,111</sup> and the putatively immunosuppressive motif in the C-terminal region of GP<sub>1,2</sub>.<sup>2,13,112</sup> In tandem with T-lymphocyte depletion, infected monocytes/macrophages release a host of soluble mediators including proinflammatory cytokines such as MIP-1 $\alpha$  and MCP-1. These cytokines usually recruit additional macrophages to infected areas and in EHF could increase the number of target cells available for viral infection and further amplify an already dysregulated host response.<sup>103</sup> Cultured primary human monocytes/macrophages are also activated upon infection resulting in an

increase of TNF- $\alpha$ , interleukin (IL)-1 $\beta$ , IL-6, and IL-8.<sup>113,114</sup> Infection by MARV led to a significant increase in release of TNF- $\alpha$  with peak values of 3 ng/mL by 12–24 hours post-infection. UV-inactivation of whole virus does not impair the activation of production of cytokines at either the transcriptional or protein level.<sup>113</sup> EBOV-infected patients also exhibit increased serum levels of various cytokines, and increased levels of IL-10, neopterin, and IL-1 receptor antagonist (IL-1RA) have correlated with fatal outcome, whilst presence of IL-1 $\beta$  and elevated concentrations of IL-6 in the plasma during the symptomatic phase have been identified as markers of nonfatal infections.<sup>115–118</sup>

Infected macrophages discovered in various tissues are thought to originate from infected circulating monocytes/macrophages that extravasate following infection.<sup>104,105,114</sup> Virus-induced cytokine release activates the endothelium and is proposed to be the trigger for extravasation. Specifically, various inflammatory mediators including TNF- $\alpha$ , IL-1 $\beta$ , and hydrogen peroxide increase the expression of various cell adhesion molecules on endothelial cells including intravascular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1) and E- and P-selectins.<sup>88</sup> In spite of the in vitro upregulation of these molecules, which mediate the binding of leukocytes to the surface of the endothelium and initiate extravasation,<sup>119–121</sup> there is a lack of leukocytic infiltrates in areas of focal necrosis, thereby suggesting a deficient immunoreaction of unknown mechanism.<sup>105</sup>

Endothelial dysfunction can lead to a multitude of vascular effects that may cause disturbances in vascular permeability or hemorrhage. During filovirus infection, the endothelium appears to be affected in two ways: directly by infection with filoviruses, leading to activation and later cell death, and indirectly by a mediator-induced inflammatory response.<sup>90</sup> In vitro virus-induced cytokine release leads to activation of the endothelium defined as increased expression and/or release of adhesion molecules as well as a breakdown of the endothelial barrier function.<sup>91,122</sup> While the molecular mechanisms for the disruption of endothelial barrier function are not completely understood, there is evidence for changes in the protein organization of the adherens junction, specifically the VE-cadherin/catenin complex.<sup>88</sup> Additionally, supernatants from MARV-infected macrophages increase the permeability of HUVEC monolayers, and this effect can be partially blocked by antibodies that neutralize TNF- $\alpha$ , suggesting a critical role for this protein in virus-induced shock.<sup>114</sup> A recent serial sacrifice experiment of EHF in monkeys revealed ultrastructural evidence of endothelial cell activation and disruption but attributes it to indirect mechanisms since they were unable to associate the changes with the presence of intracytoplasmic EBOV antigens. Overall, the data suggest that EBOV affects the function of endothelial cells in the early stages of infection and that EBOV-induced coagulopathy results primarily from vasculopathy induced by factors secreted by infected monocytes/macrophages and dendritic cells (including cytokines and tissue factor); whereas direct virus-induced cytolysis of endothelial cells plays a later, secondary role in hemorrhagic diathesis.<sup>107</sup> The fact that antigen-positive endothelial cells are a hallmark of human infection and that filoviruses readily replicate in human umbilical cord endothelial cells (HUVEC) in vitro cannot be dismissed. Whether their infection plays a major role in EBOV pathogenesis as

compared to indirect effects of mediators remains to be determined. The role of EBOV-soluble glycoproteins in endothelial activation and dysfunction is unknown. EBOV sGP was suggested to play a role in immune suppression by inactivation of neutrophils, but these data have been disputed.<sup>44,45,123</sup> The ability of sGP to function in endothelial activation has been suggested in a model by Schnittler and colleagues as a third mechanism by which the endothelium is altered during filovirus infection.<sup>91</sup> Furthermore, synthesis of full length GP<sub>1,2</sub> was found to induce cytotoxic effects in human endothelial cells, and this ability was mapped to the mucin-like domain of the protein.<sup>124</sup>

## DIAGNOSIS

An acute febrile illness with headache and diarrhea can be caused by a variety of different agents including other causes of viral hemorrhagic fever (see Chapter 65). Both occupational and travel history are imperative in narrowing the diagnosis. Rural travel, jungle or cave exposure, contact with sick humans, or contact with sick or dead primates should all raise concern.<sup>10</sup> More common causes of febrile illness that should be ruled out for travelers include rickettsioses, malaria, typhoid fever, leptospirosis, borreliosis, septicemic plague, and dysentery.<sup>125</sup>

An etiologic diagnosis should be sought at the earliest stages of illness. Virus, viral antigen, and viral RNA in serum or blood should be sought during the acute phase of illness.<sup>125</sup> The most commonly used cell line for both isolation and propagation of filoviruses is the Vero (*Cercopithecus aethiops*, African green monkey kidney) cell line, particularly the E6 clone.<sup>19</sup> In addition to Vero cells, both MA-104 and SW13, a human adrenal carcinoma cell line, have proven useful in primary virus isolation.<sup>126</sup> Filoviruses also infect primary cell cultures, particularly monocytes, macrophages, and endothelial cells.<sup>113,114</sup>

Virus can be demonstrated directly by electron microscopic analysis of tissue culture supernatants, blood, or serum, in addition to scanning of cell cultures for cytopathic effects and immunofluorescent staining of infected cells. Detection of viral antigen from infected patients may be accomplished by enzyme-linked immunosorbent assay (ELISA); in a minority of patients, if levels are low, a more sensitive method to detect viral RNA such as reverse transcriptase polymerase chain reaction (RT-PCR) is more appropriate. IgM-capture ELISA may only be positive during the early stages of convalescence, and patients can be followed for rising IgG levels to further increase confidence in the diagnosis.

## TREATMENT

There is currently no specific antiviral therapy for filovirus HF, and patient care is supportive in nature.<sup>10,127</sup> Supportive treatment should include attention to fluid and electrolyte balance, particularly with respect to potassium substitution. In several outbreaks, antibiotics were administered (tetracycline, chloramphenicol, penicillin, cephalothin, and streptomycin) but did not alter the fever or course of disease. During various outbreaks and experimentally in animal models, a number of treatments were administered in an attempt to reduce severity of disease. In particular, neutralizing antibodies specific for the viral surface glycoprotein were shown to be both protective and therapeutic in rodent models.<sup>128–130</sup>

Baboons were successfully protected from EBOV challenge, but only when large volumes of a hyperimmune horse serum were administered within 4 hours of infection with a low virus dose.<sup>131</sup> The use of horse serum in humans has been questioned, however, because horses produce a subclass of immunoglobulin (IgG<sub>1</sub>) that is highly immunogenic in humans.<sup>90</sup> The use of convalescent sera during an outbreak in Kikwit was reported as protective; however, the data were actually not useful, because the treatment was started relatively late in disease at a stage when most patients are already destined to survive.<sup>66,90,132</sup> The use of convalescent sera was also reported during the MARV outbreak in Frankfurt, Germany.<sup>127,133</sup>

Since the coagulation cascade is dysregulated during EHF (leading to disseminated intravascular coagulation, DIC), treatments to alleviate microthrombus formation have been attempted. Heparin was used to treat two surviving MARV-infected patients.<sup>125</sup> Most recently it has been shown that infection with EBOV induces overexpression of the procoagulant tissue factor in primate monocytes and macrophages, suggesting that inhibition of the tissue-factor pathway could ameliorate the effects of EBOV HF.<sup>134</sup> In further studies, macaques were administered recombinant nematode anti-coagulant protein c2 (rNAPc2), a potent inhibitor of tissue factor-initiated blood coagulation, and postexposure protection was conferred and provided a new foundation for therapeutic regimens that target the disease process rather than viral replication.<sup>135</sup> Treated animals had increased survival times with 33% survival rate and attenuation of the coagulation and proinflammatory responses.

## PREVENTION

The first attempts to develop a vaccine for EBOV began soon after the first outbreak in 1976 and used formalin-fixed or heat-inactivated virus in an attempt to confer protection to guinea pigs and nonhuman primates.<sup>90,136</sup> Despite initial optimism, the protection achieved in both studies was inconsistent, and it was later demonstrated that inactivated virus did not induce sufficient immunity to reliably protect baboons against a lethal dose of virus.<sup>137</sup>

Since the 1990s, there has been a greater effort on vaccine development particularly for EBOV. The majority of these attempts have focused on subunit vaccines that are based on one or more of the viral structural proteins. A variety of approaches including naked DNA, adenovirus, vaccinia virus, vesicular stomatitis virus, Venezuelan equine encephalitis virus replicons and virus-like particles have been used as mechanisms to deliver GP<sub>1,2</sub>, NP, VP24, VP30, VP35, and/or VP40.<sup>138–145</sup> The efficacy and specific details of these vaccine strategies have been recently reviewed in great detail.<sup>90,145</sup> These studies, as well as therapeutic studies, have led to an important conclusion about animal models: interventions in the mouse are most successful; success is somewhat more difficult to achieve in the guinea pig; and the primate model is most demanding. The only successful EBOV vaccine in nonhuman primates is the adenovirus-vectored GP gene. It protected guinea pigs and macaques against lethal challenge and has been inoculated into humans in a phase I trial.<sup>139,146</sup> The difficulty of obtaining an Ebola vaccine candidate and the adenovirus success have important

implications for vaccine development against viruses that have effective escape hatches against the immune response if we can understand the mechanisms at play. There are still formidable problems to overcome in a successful human Ebola vaccine because of the difficulties in defining a target population for efficacy testing. Nevertheless, with today's hectic travel, the threat of bioterrorism, social unrest in the endemic areas, and the increase in naturally occurring epidemics, a vaccine may well be needed. Possible targets would include nonhuman primates in endemic areas, medical personnel in Africa, and research workers worldwide.<sup>90</sup>

# Yellow Fever

ANTHONY A. MARFIN  
RACHEL BARWICK EIDEX  
THOMAS P. MONATH

## INTRODUCTION

Yellow fever is the first-described hemorrhagic fever; in its most fulminant form, it is characterized by severe hepatic and renal injury, hemorrhage, and high mortality. Yellow fever virus, the causative agent of this illness, is the prototype member of the *Flavivirus* genus. Yellow fever virus transmission occurs only in South America and sub-Saharan Africa. Despite this restricted range, it is important for physicians worldwide to consider yellow fever because of its potential to cause large urban outbreaks in areas outside of South America and Africa, because of the risk to travelers in endemic areas, and because of serious adverse events following immunization (AEFI) with yellow fever vaccine.

## AGENT

### Viral Structure

Yellow fever virus is the prototype member of the genus *Flavivirus* in the family *Flaviviridae* that includes more than 70 small (40 to 60 nm), single-stranded, positive-sense RNA viruses, most of which are arthropod-borne. Sequence analysis of the envelope gene revealed that yellow fever virus diverged from other mosquito-borne flaviviruses (e.g., dengue virus) approximately 3000 years ago.<sup>1</sup>

The 10.9-kilobase (kb) genome of yellow fever is organized into a single 10.2-kb open reading frame (ORF) flanked by a short 5' noncoding region (NCR) and a longer 3' NCR.<sup>2-4</sup> Both NCRs have highly conserved, complementary sequences that are important in the formation of a circular genome after cell entry to promote replication. Mutations or deletions in these complementary sequences affect replication and virulence. In addition, there are differences in these NCRs between yellow fever virus strains. The 5' NCR is similar for all strains, but the 3' NCR includes imperfect repeat sequences of 42 nucleotides. South American strains have one copy of this sequence, East African strains have two, and West African strains have three. The differences in repeat sequences appear to be due to evolutionary divergence, and there is no difference in the virulence or replication efficiency associated with the different number of sequences. The ORF consists of three structural protein genes (i.e., capsid [C], premembrane [prM], and envelope [E]) followed by seven nonstructural (NS) protein genes (NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5). These 10 genes are translated into a single polyprotein

and then cleaved into individual proteins. The C, prM, and E proteins are present in the mature virion. NS proteins are not present in the mature virion but are produced immediately after infection when they are responsible for replication and polypeptide processing.

The viral envelope is a lipid bilayer derived from the host cell with E protein dimers on the surface. The E protein is responsible for the initial attachment and infection, is the principal target of the host's immune response, and is considered the primary virulence factor. A highly conserved stretch of 14 amino acids in the E protein is responsible for fusion of the virus with the lysosomal membrane of the infected cell. The rearrangement of the E proteins to expose the fusion region is absolutely required for the virus to enter the cell cytoplasm. E gene mutations, especially in the fusion domain, greatly alter these biologic functions.<sup>5,6</sup> In addition, because the E protein contains epitopes against which neutralizing activity is directed, anti-E antibody provides protection by interfering with attachment and fusion.<sup>7</sup> Theoretically, major mutations in the E gene can reduce the protective qualities of anti-E antibody acquired by previous yellow fever infections or immunization; such a mutation has not yet been reported.

NS1 is critical to intracellular virus RNA replication, is released extracellularly, and is expressed on the surface of infected cells (Table 71-1). The secreted form has both virus-specific and cross-reactive epitopes. Antibodies to NS1 do not neutralize virus infectivity but provide protection by complement-mediated lysis of infected cells that express the NS1 epitope on their surface.<sup>8</sup> The E, NS1, NS2A, and NS3 proteins have a dominant cytotoxic T-cell epitope; this suggests that T-lymphocyte responses to yellow fever virus play a role in long-term immunity.<sup>9</sup> NS2B and NS3 form a critical enzyme complex that includes a serine protease responsible for post-translational cleavage of the virus polyprotein, an RNA helicase, and an RNA triphosphatase. The NS3 gene sequence is highly conserved at the sequence level. The protein is on the host cell surface and, because NS3 contains cytotoxic T-cell epitopes, infected cells are eliminated by cell-mediated immunity.<sup>9,10</sup> NS4A and NS4B are hydrophobic, membrane-associated proteins that regulate RNA replication. NS5 protein is also highly conserved and functions as the RNA-dependent RNA polymerase in virus replication.

## Replication

After attachment to an as yet undefined cell receptor, virus is transported intracellularly within a phagosome. The acidic environment in the phagosomes results in fusion of the virus membrane with the vesicle membrane and release of the nucleocapsid into the cytoplasm. The uncoated, positive-sense RNA (i.e., messenger sense) is immediately translated to synthesize RNA-dependent RNA polymerase, RNA helicase, and RNA triphosphatase, which replicate full-length negative RNA strands. These negative strands serve as templates for positive RNA strands that are assembled into virions in the endoplasmic reticulum (ER) and undergo exocytosis.

## Genetic Variation

Based on plaque-reduction neutralization assays, the *Flavivirus* genus was divided into eight antigenic complexes

**Table 71-1** Functional Description of 10 Genes/Proteins That Are Found in Yellow Fever Virus and Other Members of the Genus *Flavivirus*

Gene/Protein	Primary Function	Comments
Capsid (C) Premembrane (prM)	With genomic RNA, forms nucleocapsid Stabilizes E protein during exocytosis	Cleaved before release to form pr and M proteins. pr released to extracellular medium, M retained in viral envelope; failure to cleave can affect antigenicity and conformation of E protein and may reduce infectivity of virus
Envelope (E)	Receptor-mediated cell attachment and cell fusion	Forms E protein dimers within lipid bilayer of viral envelope and can be inactivated with organic solvents and detergents
NS1	RNA replication	Monomers released extracellularly and form dimers to be expressed on the surface of infected cells; antibodies to NS1 do not neutralize infectivity but do provide protective immunity through complement-mediated lysis of infected cells <sup>68</sup>
NS2A	RNA replication	Interacts with NS3, NS5, and 3' NCR to replicate; critical for virion assembly and release
NS2B	See NS3	Forms complex with NS3 to perform functions
NS3	Multifunction: Serine protease, RNA helicase, RNA triphosphatase	Serine protease performs post-translational cleavage of the viral polyprotein; RNA helicase and RNA triphosphatase critical to RNA replication; NS3 highly conserved base sequence; target of attack for cytotoxic T cells <sup>14,38</sup>
NS4A	Regulate RNA replication	Hydrophobic, membrane-associated protein
NS4B	Regulate RNA replication	Hydrophobic, membrane-associated protein
NS5	RNA-dependent RNA polymerase	In addition to polymerase function, functions as a methyltransferase for 5' cap methylation; like NS3, highly conserved base sequence

and several other antigenically unique viruses, such as yellow fever virus.<sup>11</sup> Gene sequencing confirmed these relationships, grouped yellow fever with nine other flaviviruses (Banza, Bouboui, Edge Hill, Jugra, Saboya, Potiskum, Sepik, Uganda S, and Wesselsbron viruses), and showed that yellow fever is most closely related to Sepik virus from New Guinea.<sup>12</sup> In addition, these analyses suggest that yellow fever virus is the most distantly related mosquito-borne flavivirus.<sup>1,12</sup>

Seven genotypes have been distinguished by nucleotide sequencing, but they represent a single serotype. Genomic analyses support the concept that yellow fever virus arose in Africa and that East and West African genotypes diverged prior to the introduction of the virus to the Americas.<sup>13,14</sup> Genomic analyses identified two genotypes in West Africa and three in Central and East Africa.<sup>15</sup> Within each African genotype, there is little genetic variation. This is likely due to the yellow fever virus' high-fidelity RNA-dependent RNA polymerase.<sup>16</sup> Unlike the error-prone replication seen in other RNA viruses that results in one mutation out of every 10<sup>4</sup> bases replicated, yellow fever virus averages two mutations every 10<sup>7</sup> bases. Yellow fever virus has achieved only a modest degree of genetic variation following introduction to the Americas. In the Americas, two genotypes have arisen despite significant geographic overlap.<sup>17</sup> Limited genetic analyses of M, E, NS5, and the 3' NCR comparing the South American genotypes showed that these genotypes

represent divergent lineages resulting from geographic and temporal separation and infrequent recombination. There is no difference in the resulting human disease associated with these seven YF variants, but it is unknown whether the highly variable mortality in different epidemics is due to genomic variation.

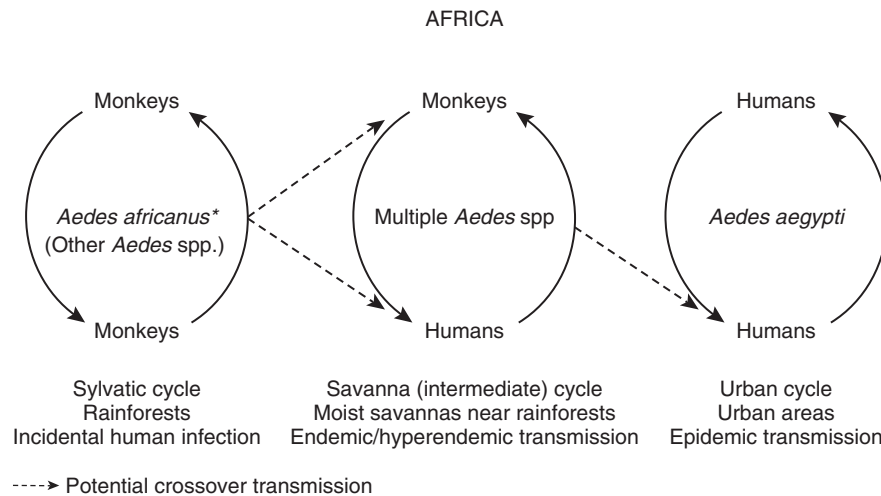

## EPIDEMIOLOGY

### Transmission Patterns and Ecology

In Africa, three transmission cycles can be distinguished: the sylvatic, urban, and savanna cycles (Fig. 71-1). In South America, only sylvatic and urban cycles have been identified (Fig. 71-2). In all three cycles, yellow fever virus is transmitted between primates by diurnally active tree hole-breeding mosquitoes. Neither the virus nor the clinical disease differs in these three cycles, but identifying the type of transmission cycle is important for disease control. In all of these cycles, endemic and epidemic disease patterns can occur.

The sylvatic cycle is the predominant transmission cycle in equatorial rain forests in Africa and South America. The cycle is maintained among monkeys by tree hole-breeding mosquitoes. Humans are incidentally infected when they enter the forest or when viremic monkeys exit the forests and infect mosquitoes at the forest fringe. The primary sylvatic

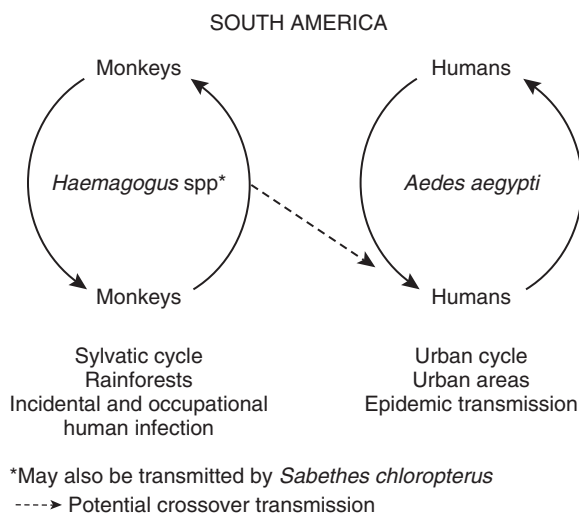

**FIGURE 71-1** African transmission cycles include a sylvatic cycle, a savanna (or intermediate) cycle, and an urban cycle. In each cycle, the mosquito vectors are tree hole-breeding *Aedes* species. The urban cycle, characterized by human-to-human transmission mediated by *Aedes aegypti*, may begin when a viremic human either incidentally infected in the rain forest or infected during endemic transmission in the savanna travels to urban areas.

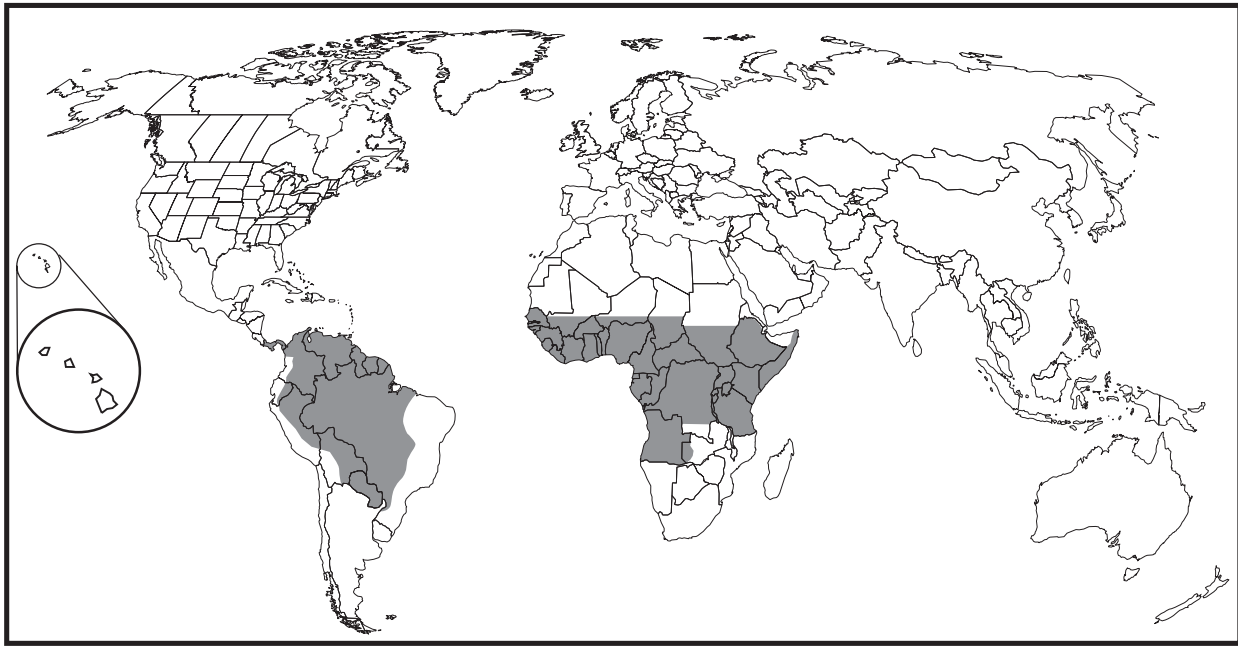

vectors are mosquito species that occur in tree canopies—*Aedes africanus* in Africa and *Haemagogus* species in South America. Other African mosquito species implicated in transmission include *Aedes furcifer*, *Aedes vittatus*, *Aedes luteocephalus*, and *Aedes simpsoni*; in South America, in addition to *Haemagogus* species, *Sabethes chloropterus* may be involved. Many nonhuman primate species are susceptible to yellow fever infection. Most African species do not become ill but develop viremia sufficient to infect mosquitoes; however, in South America several species develop lethal infections. Depletion of vertebrate hosts through natural immunization or death during epizootics is a factor in the cyclic disappearance of yellow fever. In many areas, deforestation and hunting

have reduced monkey populations, and human beings have become the primary hosts in the transmission cycle. The sylvatic yellow fever cycle may be active but unrecognized in forested areas of countries within the yellow fever endemic zone. Evidence suggests that yellow fever virus will be maintained in one place until the amplifying primates are immune and then reemerge in areas where susceptible primates live. Disease may not be detected for years but then will reappear. Yellow fever virus is maintained through periods during which mosquitoes are absent (e.g., the dry season) by means of transovarial transmission. (i.e., vertical transmission through infected eggs). Sylvatic transmission can most effectively be prevented by vaccination of human populations at risk of exposure.

Urban yellow fever refers to settings in which human-to-human transmission is mediated by *Aedes aegypti*, a domestic mosquito associated with human habitation and unpolluted collections of water. In areas where *Ae. aegypti* was eliminated, urban yellow fever disappeared. In the mid-1900s, Panama, Brazil, Ecuador, Peru, Bolivia, Paraguay, Uruguay, and Argentina successfully eradicated this vector; no urban epidemics occurred. The last clearly documented *Ae. aegypti*-borne yellow fever epidemic in the Americas occurred in Trinidad in 1954. During the past 20 years, many countries that had previously eradicated *Ae. aegypti* have been reinfested.<sup>18,19</sup> Large urban outbreaks have not yet occurred, but *Ae. aegypti* mosquitoes were suspected as the vector during outbreaks in Bolivia in the late 1980s through the mid-1990s. In other South American countries (e.g., Venezuela, Guyana, and Surinam), eradication never occurred. These countries remain infested with *Ae. aegypti* in cities near areas with enzootic activity and have great potential for urban epidemics. In Africa, *Ae. aegypti* eradication never occurred, and yellow fever epidemics continued to occur in cities, towns, refugee camps, and rural villages where the vector is prevalent.<sup>20,21</sup> Because of an association between population density and the presence of *Ae. aegypti*, massive epidemics have occurred in Africa. In Nigeria in 1987, an epidemic of an

**FIGURE 71-2** South American transmission cycles include a sylvatic cycle and an urban cycle. In the sylvatic cycle, the mosquito vectors are treetop feeding *Haemagogus* or *Sabethes* species. The urban cycle, characterized by human-to-human transmission mediated by *Aedes aegypti*, may begin when a viremic human either incidentally or occupationally infected in the rain forests travels to urban areas.

### Yellow Fever

■ Yellow Fever

Countries and regions with yellow fever virus transmission. Shading is based on recent reports of human yellow fever infections or on the continued presence of ecological factors associated with yellow fever virus transmission in areas with historical reports of human yellow fever infections (Adapted by Jodi Udd. From the Centers for Disease Control and Prevention: Health Information for International Travelers, 2005–2006 [Yellow Book]. A frequently updated version of the CDC's Yellow Book can be found at <http://www.cdc.gov/travel/yb/index.htm> and should be used to determine a person's actual need for yellow fever immunization.)

estimated 39,000 cases and 8400 deaths occurred in urban areas. Other major *Ae. aegypti*-borne epidemics occurred in 1965 and 1979 in Senegal and in 1971 in Angola.

Because of the mobility of potentially viremic humans, urban yellow fever outbreaks may occur in cities that are remote from sylvatic areas. When considering the potential for large urban yellow fever epidemics in South America, one can point to previous outbreaks of dengue, a flaviviral disease transmitted by *Ae. aegypti*. To eradicate *Ae. aegypti* again will be difficult because of insecticide resistance, human population growth, and the high cost. Thus, the scene is set for large urban outbreaks in the Americas. Without reduction of *Ae. aegypti*, urban yellow fever can only be prevented by vaccinating at-risk human populations.

In Africa, a savanna cycle is recognized in areas where humans live in moist grasslands bordering African rain forests where *Aedes* mosquitoes feed on both humans and monkeys. This is sometimes called the intermediate zone because it serves as a link between primates in the deep forest and people in adjacent African villages. In West Africa, the principal vectors in this zone include *Ae. fuscifer*, *Ae. vittatus*, *Ae. luteocephalus*, and *Ae. africanus*. In East Africa, *Ae. africanus* and *Ae. simpsoni* are the principal vectors. During the wet and early dry seasons, high vector density occurs and mosquitoes readily enter houses. During these periods, virus transmission rates far exceed that found in sylvatic zones.

### Mosquito Vectors

Tree hole-breeding mosquitoes are the primary vectors involved in the replication of virus and transmission between

vertebrate hosts. Uninfected female mosquitoes become infected when they feed on an infected host with a viremia of at least  $10^4$  pfu/mL. After a 7- to 14-day incubation period in the mosquito, high virus titers are present in the salivary glands. During subsequent blood meals, virus is transmitted to a new vertebrate host. In addition, yellow fever virus can be transmitted transovarially, allowing viral survival in the absence of adult mosquitoes. Some populations of mosquitoes transmit yellow fever virus more efficiently than others. In the laboratory, the ability of *Ae. aegypti* to infect mice is variable and low, between 30% and 80%. Field studies during large African epidemics have shown that *Ae. aegypti* is an inefficient vector even during epidemics.<sup>22</sup> Despite the inefficiency, the anthropophilic nature of the vector and the high densities of the mosquito in urban areas make it an excellent vector for human-to-human transmission. It has been suggested that such inefficiency of mosquito vector strains selects greater virus virulence. For example, the low transmission efficiency of *Ae. aegypti* may select viruses that achieve higher viremia, thus increasing the pathogenicity of the virus strain.

### Vertebrate Hosts

Primates are the only vertebrate hosts implicated in the yellow fever transmission cycle. In general, viremia is short (i.e., 2 to 5 days), although it can be 9 days in colobus monkeys. Infected primates either die or develop lifelong protective immunity. Except for the galago (*Galago senegalensis*), African monkeys generally become viremic but do not develop illness. Primates support the natural transmission cycle, but yellow fever virus can infect nonprimate species.

Viscerotropic disease (infection of liver, heart, and kidneys) occurs in primates, hedgehogs, and golden hamsters. In these species, the liver is primarily involved, and the virus does not cause encephalitis. Yellow fever virus does cause encephalitis in mice, hamsters, and guinea pigs after intracerebral inoculation. A number of vertebrates (e.g., sloths) have been found to have antibodies against yellow fever virus, but because of their low viremia they are unlikely to be important in maintaining virus transmission.

### Geographic Distribution and Incidence

From 1985 to 1999, 25,846 yellow fever cases were reported to the World Health Organization (WHO); of these, 22,952 (89%) were reported from sub-Saharan Africa, where it affects 34 countries, and the remainder from 14 countries in tropical South America. In Africa, the number of reported cases varied from 0 to 5000 per year and suggests significant inconsistencies in surveillance and reporting. In South America, up to 300 cases per year have been reported to WHO. Case fatality is highly variable but usually approximately 20%; higher rates have been reported. Because most yellow fever cases are not reported, WHO estimated that the true incidence may be 200,000 cases and 30,000 deaths annually.<sup>23,24</sup> In addition to underreporting “classic” yellow fever cases, the number of yellow fever viral infections is not known but believed to be much higher. The ratio of classic yellow fever cases to the number of infections is estimated to be approximately 1:10, but this may vary greatly.

In Africa, of the 22,952 cases reported from 1985 to 1999, 5357 (23%) were fatal. The majority of outbreaks have been reported from West Africa; fewer outbreaks have been reported from Central and East Africa. This is due to a combination of factors, including higher densities of humans and *Ae. aegypti*, creating greater potential for human-to-human transmission in the west. Within Africa, Nigeria has the largest number of reported cases due to a series of epidemics from 1986 to 1994. Since 1990, outbreaks have occurred in many West African countries, including Cameroon (1990), Ghana (1993–1994, 1996), Liberia (1995, 1998, 2004), Gabon (1994), Senegal (1995–1996, 2002), Benin (1996), Guinea (2000–2001), Cote d'Ivoire (2001), and Burkina Faso (2004). During West African outbreaks, up to 3% of the population may develop yellow fever and 20% is infected. Because the population is regularly exposed in and around villages, children without naturally acquired immunity are at highest risk of infection and illness.

In East Africa, outbreaks are less frequent but have been reported from Sudan in 1940, 1959, and 2004; Ethiopia in 1960 and 1966; and Kenya in 1936 and 1992–1993. Although no human disease was reported in the intervening years, low-level virus transmission occurs. In East African countries where serosurveys were performed between outbreaks, people acquired yellow fever virus-specific antibody, showing that inapparent or mild infections occurred in the absence of recognized disease. Nonetheless, East African transmission is likely also lower due to the low vector competence of *Ae. aegypti* and *Ae. simpsoni* subpopulations.

In South America, most yellow fever cases are reported from the Orinoco, Amazon, and Araguaia river basins and contiguous grasslands. Between 1985 and 1999, 2894 cases

were reported; of these, 1761 (61%) were fatal. This high fatality rate is likely due to the increased confirmation of fatal cases using histopathologic examination of liver tissue rather than greater virus virulence or poorer medical treatment. This has led to speculation that the true incidence of yellow fever in South America may be 10-fold greater than reported numbers of cases. Peru and Bolivia had the highest incidence; this is attributed to low vaccination coverage. In South America, yellow fever virus is transmitted in sparsely populated forested areas rather than urban areas. As a result, the highest incidence is among males aged 15 to 45 years who are agricultural and forest workers. In Brazil, most cases are reported from the Amazon and western Brazil; however, cases have been reported from Sao Paulo, Bahia, Tocantins, and Goias states. Also, in 1998, the first cases of yellow fever were reported in French Guiana since 1902.<sup>25</sup> In addition to the increased number of cases in recent years, *Ae. aegypti* has reinfested many urban centers in South America, and there is now the potential that urban yellow fever will return to the Americas.

Yellow fever has never emerged in Asia. Because urban areas in Asia have *Ae. aegypti* that is capable of transmitting yellow fever virus and a large susceptible human population, Asia is vulnerable to the introduction of the virus. As a result, India and other Asian nations require vaccination of travelers from yellow fever-endemic regions. Possible explanations for the absence of yellow fever virus in Asia include immunologic cross-protection provided by previous dengue virus infections, low vector competence of local *Ae. aegypti* populations, or the occurrence of yellow fever in remote African and South American areas populated by people who do not travel by air and are unlikely to spread infection.

### Seasonality

The ecology of yellow fever virus is complex, and many factors contribute to yellow fever virus transmission. In general, virus activity increases when temperature, humidity, and rainfall increase through effects on mosquito abundance. In South America, yellow fever incidence is highest during months of high rainfall, humidity, and temperature (January to May). This corresponds to periods of increased activity and reproduction of *Haemagogus* mosquitoes, a mosquito dependent on accumulated water in tree hole-breeding sites. During this time, human exposure to potentially infected mosquitoes is also increased during agricultural activities.

In the savanna zone of West Africa, yellow fever cases begin to appear during the midrainy season (August). Peak occurs during the early dry season (October), a period that corresponds to the period of maximum longevity of mosquito vectors. Because *Ae. aegypti* breeds in receptacles used for water storage, its activity and reproduction patterns are less dependent on rainfall. As a result, when *Ae. aegypti* is involved in virus transmission, yellow fever may also occur in the dry season in both rural and urban areas.

### Disease Susceptibility and Risk Factors for Human Infection

Age, sex, and occupation affect the distribution of yellow fever cases and differ in Africa and South America. In South America, *Haemagogus* mosquitoes that previously fed on

viremic monkeys in the rain forest canopy transmit virus to humans. Human infection is linked to occupational activities such as forest clearing, lumbering, and road construction; up to 90% of yellow fever cases are young men. In these settings, virus-specific antibody is 2.5 to 7.5 times more common in males than females.<sup>26</sup> The age and sex distribution of sylvatic yellow fever cases differs from that observed during the *Ae. aegypti*-borne epidemics in South America in the early 20th century. During these epidemics, because *Ae. aegypti* breeds around houses, a higher prevalence of infection occurred among children and women.

In Africa, sylvatic *Aedes* species reach high densities in the moist savanna and enter villages. In these settings, the prevalence of infection is higher in children and women, and the prevalence of naturally acquired immunity increases with age. During outbreaks, children are at highest risk for infection and disease. A high attack rate in children (>70%) typifies areas where older people are protected by pre-existing immunity from naturally acquired infections or yellow fever vaccination campaigns.

DISEASE

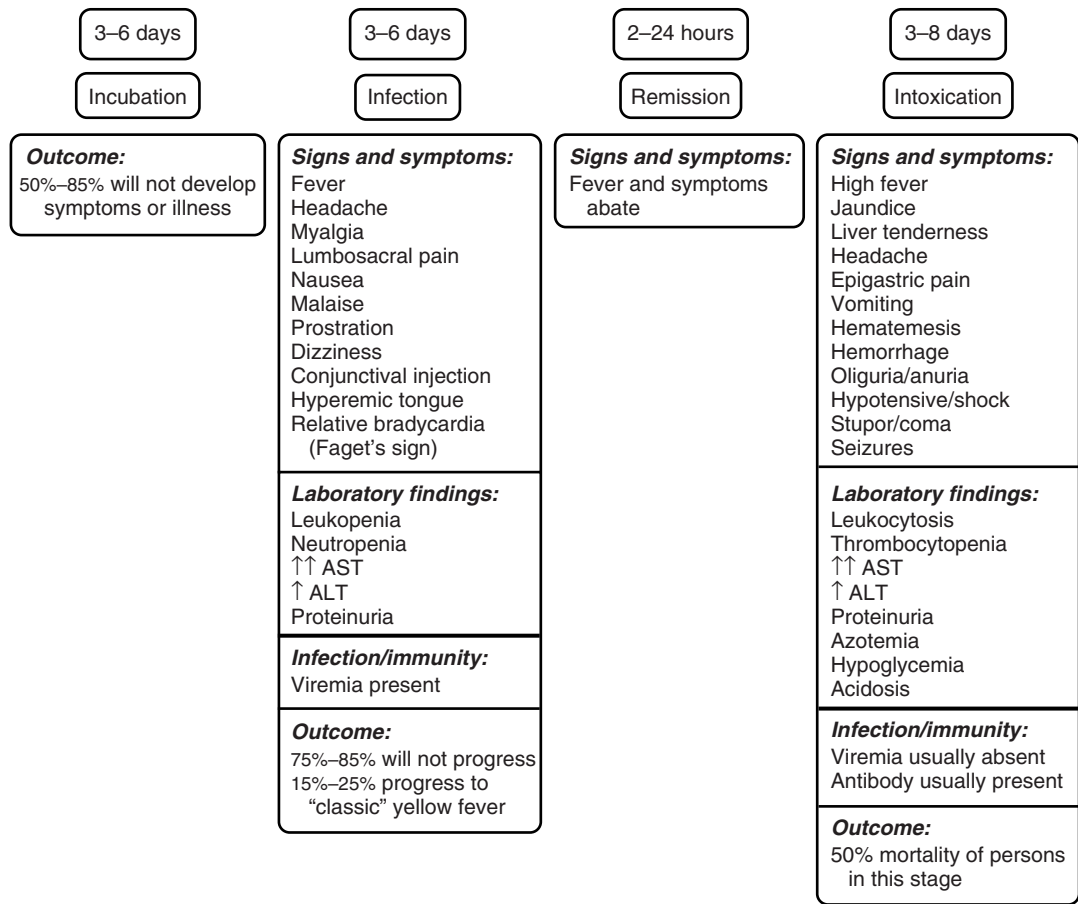

Clinical manifestations of yellow fever viral infection are broad and include asymptomatic infection; abortive infection

with nonspecific symptoms of viral illness (i.e., low-grade fever, myalgia, and headache); and classic yellow fever, a clinical syndrome of multiple organ system failure (MOSF) with hemorrhage, liver failure, and renal failure (Fig. 71-3). These variable manifestations make the diagnosis of less severe and sporadic infections difficult, resulting in an underestimate of morbidity and an overestimate of case fatality rates.

Triphasic Disease

After a 3- to 6-day incubation, it is estimated that 15% to 50% of infected people develop illness, beginning with the abrupt onset of fever, chills, and headache. Of those who develop any illness, approximately 75% to 85% will abort their infection and recover without developing classic yellow fever. The remaining 15% to 25% who become ill develop the syndrome known as yellow fever.<sup>26</sup> Following incubation, classic yellow fever is characterized by three clinical illness stages: infection, remission, and intoxication (see Fig. 71-3).

The first clinical period, the period of infection, lasts 3 or 4 days and is characterized by viremia and the pathophysiologic response to this viremia. Illness onset is abrupt, with fever of 39°C or higher, chills, malaise, headache, low back and knee pain, generalized myalgia, nausea, and dizziness. On examination, the patient has a heart rate lower than would

**FIGURE 71-3** Stages of yellow fever infection showing the duration, major clinical and laboratory findings, and outcome of each stage. (Modified from Monath TP: Yellow fever: An update. Lancet Infect Dis 1:11–20, 2001)

be expected for the degree of fever (Faget's sign) and congestion and erythema of the conjunctivae, tongue, and face. Temperatures up to 40.5°C are associated with severe illness and poor outcome. Children 5 years old or younger may experience febrile convulsions. Laboratory abnormalities include leukopenia ( $1.5$  to  $2.5 \times 10^3/\mu\text{L}$ ) with a relative neutropenia. Jaundice or hepatocellular enzyme elevation are rarely present during this period but may begin 2 or 3 days after illness onset.<sup>27</sup> In addition, proteinuria may be severe and is one of the few specific clinical findings during this early phase. Peak viremia occurs on the second or third day of illness, and infected people may serve as a source of infection for mosquitoes that poses a public health risk.<sup>28</sup>

The period of infection may be followed by a distinct period of remission when fever and other constitutional symptoms abate for up to 48 hours. Viremia may still be present during this period but is usually waning. Most patients will go on to recovery from the acute illness. Because they remain anicteric and the specificity of these early clinical signs are poor, it is difficult to diagnose these milder yellow fever viral infections clinically. In patients who do not abort their infection, fever will reappear and the patients will progress to the more fulminant period of intoxication.

Approximately 15% to 25% of people who develop any clinical symptoms (or 10% of all infected people) progress to the period of intoxication. This generally occurs 3 to 6 days after illness onset and lasts for approximately 3 to 8 days. During this period, viremia disappears, antibodies appear, and the signs of classic yellow fever (jaundice, renal failure, and hemorrhage) appear. It is heralded by the return of fever, relative bradycardia, nausea, and vomiting. In addition, patients develop epigastric pain, jaundice, oliguria, and hemorrhagic signs and rapidly progress to MOSF dominated by hepatic, renal, hematologic, and cardiovascular involvement. Serum concentrations of hepatocellular enzymes, aspartate aminotransferase (AST) and alanine aminotransferase (ALT), peak early in this phase. In yellow fever, AST levels are generally greater than ALT levels, in contrast to viral hepatitis, in which the reverse is true. In fatal yellow fever cases, the AST and ALT levels are usually greater than 2700 and 600 U, respectively. Direct bilirubin levels are typically between 5 and 10 mg/dL and higher in fatal cases compared to nonfatal cases.<sup>29,30</sup>

Renal dysfunction is characterized by albuminuria, microscopic hematuria, reduced urine output, and rising blood urea nitrogen and creatinine. As a result of increased glomerular permeability, albumin concentrations in the urine are typically in the nephrotic range (3 to 5 g/L) and may reach 20 g/L. Serum creatinine levels are three to eight times normal. Despite the severity of the renal disease and albuminuria, the extravascular fluid accumulations that accompany many hemorrhagic fever viruses (i.e., edema, ascites, and pleural effusion) are not seen in yellow fever. Also, despite the apparent severity of renal failure, dialysis is not usually needed.<sup>31</sup>

In addition to the pathologic changes in the liver and the kidneys, there are widespread petechiae and hemorrhages on mucosal surfaces, in the skin, and within other organs. The hemorrhagic signs include hematemesis (coffee grounds emesis), melena, hematuria, metrorrhagia, petechiae, ecchymoses, epistaxis, and oozing of blood from the gums and needle puncture sites. Laboratory findings reflect the marked dysfunction of the hematologic system and coagulation cascade

that contributes to the hemorrhagic signs. These include thrombocytopenia, prolonged clotting and prothrombin times, and reductions in clotting factors synthesized by the liver (factors II, V, VII, IX, and X). Some patients develop disseminated intravascular coagulation (DIC) marked by diminished fibrinogen and factor VIII and the presence of fibrin split products.

Myocarditis occurs in many patients and undoubtedly contributes to cardiovascular dysfunction. The electrocardiogram may show sinus bradycardia without conduction defects and ST-T abnormalities presumably due to virus replication and direct viral injury to the myocardium. Bradycardia may contribute to the physiologic decompensation associated with shock and metabolic acidosis in severe cases.

Although central nervous system (CNS) signs, such as delirium, seizures, and coma, may be present, there is little to suggest direct viral invasion of the CNS. In the most severe cases, no pleocytosis is present, although there may be modest elevations of protein in the cerebrospinal fluid (CSF). In pathologic examinations, no inflammatory changes are present in the brain. Because true encephalitis is rare, it is likely that the CNS signs are the result of poor cerebral perfusion, cerebral edema, cytokine dysregulation, or metabolic abnormality.

### Risk Factors for Illness

Older people and males are at risk for a more severe clinical course. Studies of the clinical course among immunosuppressed people are not available. Protein-calorie malnutrition has been associated with failure to respond immunologically to yellow fever vaccine, but there are no reports that malnourished people have more severe disease caused by wild-type yellow fever virus. Similarly, the immune response to yellow fever vaccine is significantly impaired in pregnant women compared to nonpregnant women.<sup>32</sup> This difference has been attributed to the immunosuppression associated with pregnancy, but pregnancy has not been reported as a risk factor for more severe disease. Human immunodeficiency virus (HIV) infection may be an important risk factor for increased yellow fever viremia following infection, disease severity, and risk for AEFI after yellow fever vaccination. A poor immune response has been noted following yellow fever 17D vaccination of HIV-infected travelers and children,<sup>33</sup> but there has been only a single published report of a severe AEFI in an HIV-infected person.<sup>34</sup>

### Mortality

Nearly 50% of patients who develop hepatic and renal failure and anuria die. Disease severity and mortality are highest in older adults.<sup>35</sup> Death is preceded by profound hypotension and shock that is difficult to manage with fluids and vasopressors. This condition appears to be due to an outpouring of proinflammatory cytokines that are produced by infected and injured macrophages and lymphocytes rather than extravascular fluid loss. In addition to hypotension, worsening jaundice, and acute renal failure, signs of cerebral edema (e.g., hypothermia, coma, and Cheyne-Stokes respirations) are associated with impending death. Other signs include hypoglycemia, uncorrectable acidosis, leukocytosis, hyperkalemia, agitated delirium, intractable hiccups, and seizures.

Complications of yellow fever among survivors include superimposed bacterial pneumonia, parotitis, and sepsis. Late deaths during convalescence have been attributed to myocarditis, arrhythmia, or heart failure. Convalescence may be associated with weakness and fatigability lasting weeks, but healing of the liver and kidney is typically complete without postnecrotic fibrosis. In some cases, jaundice and elevated hepatocellular enzymes may persist for months.

## **PATHOGENESIS AND IMMUNITY**

### **Pathogenesis and Pathophysiology**

Although yellow fever has features in common with other hemorrhagic fever or hepatitis viruses, the type and severity of hepatic injury and accompanying renal injury are pathologically distinct.<sup>36,37</sup> Kidney, liver, and myocardial damage is due to the direct injury of viral replication. In addition to the viral-induced pathologic changes in the liver and kidneys, there are profound ischemic changes in other organs resulting from widespread hemorrhages and the resulting profound shock. In addition, there may be mitochondrial damage that results in increased membrane permeability and apoptotic cell death. Interestingly, most of this injury occurs during the period of intoxication, when yellow fever viremia is usually absent and virus-specific antibodies are developing.

### **Pathogenesis of Hepatic Failure**

Unlike hepatitis, in which ballooning necrosis and cell-mediated inflammation are the primary cause of cell damage, the liver destruction of yellow fever results from apoptosis and is not associated with significant inflammation. Nevertheless, markers of hepatic dysfunction, such as elevated bilirubin and hepatocellular enzymes, correlate directly with disease severity and prognosis. The five central features of yellow fever liver pathology are eosinophilic degeneration of hepatocytes and Kupffer cells, midzonal (zone 2) hepatocellular degeneration, the absence of inflammation, microvesicular fatty change, and retention of the reticulin structure with return to normal histology in survivors. A unique feature of hepatic injury in yellow fever is the midzonal distribution with sparing of cells around the central vein and portal tracts. Although this unique distribution may be the result of poor tissue perfusion of this region and ischemia, yellow fever virus antigen and RNA have been observed disproportionately in the hepatocytes in the midzone, suggesting that these cells are more susceptible to virus replication.<sup>37,38</sup> Although, on average, up to 80% of hepatocytes may be destroyed, the livers of survivors heal without postnecrotic fibrosis.

### **Pathogenesis of Renal Failure**

The pathogenesis of renal injury in humans is poorly understood but appears multifactorial. In studies of non-human primates, although viral antigen can be detected in the kidney parenchyma, the initial oliguria does not appear to be due to direct renal injury by the virus.<sup>38</sup> Instead, the initial injury appears to be due to renal ischemia that is out of proportion to the degree of hypovolemia that is present and

more likely attributable to tumor necrosis factor (TNF) and other proinflammatory cytokines. At death, immunohistochemistry (IHC) can detect antigen in glomeruli and renal tubular cells, suggesting a role for direct viral injury. In addition, renal failure may be due to the severe hepatic injury (i.e., hepatorenal syndrome) that alters salt and water regulation and can be present in the absence of renal pathology. Prior to death, oliguria worsens and is often accompanied by proteinuria, azotemia, acidosis, shock, hyperkalemia, and severe tubular necrosis.

### **Pathogenesis of Myocardial Injury**

Myocardial injury in yellow fever appears to be due to viral replication within the myocardial cells, where viral antigen can be demonstrated by IHC. Myocardial cells undergo similar apoptotic changes as seen in liver and kidney, as well as microsteatosis. As in other organs, damage may be patchy, and there is no significant inflammatory response. As in the liver, the reticulin structure is preserved, and no fibrosis occurs after recovery. Lesions have been noted in the conduction system. These changes often result in conduction and other rhythm disturbance abnormalities. When bradycardia is present, it may contribute to the physiologic decompensation associated with hypotension, reduced perfusion, and metabolic acidosis in severe cases. The pathological changes in these major conduction pathways suggest a physiologic basis for late deaths attributed to cardiac arrhythmias.

### **Coagulation Defects**

Coagulopathy is the result of two processes—decreased hepatic synthesis of coagulation factors and the presence of DIC, a process of accelerated consumption of coagulation factors and platelets. The basis of DIC is the unregulated and excessive generation of thrombin that results in the consumption of coagulation factors such as fibrinogen and factor VIII. In addition, thrombin binds thrombin receptors on platelets to induce platelet activation and aggregation to endothelium and initiates simultaneous coagulation and fibrinolysis. Similar events occur in people with dengue hemorrhagic fever (DHF), in which liver function and synthesis of clotting factors are well maintained compared to yellow fever. In DHF, the events are mediated through the intrinsic coagulation pathway and activated by cytokines, particularly TNF, interleukin (IL)-6, and IL-1. It is not known whether the same mechanisms are operating in yellow fever. In studies of yellow fever virus-infected monkeys, severely ill animals have depressed levels of all clotting factors, particularly fibrinogen and factors V, VII, VIII, and X. This situation suggests that yellow fever does not specifically activate the intrinsic pathway, and that the major cause of bleeding is decreased synthesis of clotting factors.

### **Other Hematologic Abnormalities**

Leukopenia, particularly neutropenia, is an early finding in yellow fever infection. IFN may contribute to leukopenia and thrombocytopenia by bone marrow suppression and induction of a wide array of cytokines. Neutropenia and thrombocytopenia also may be caused more directly by

cytokines such as TNF, IL-1, or IL-6 released during the initial infection. The spleen and lymph nodes undergo profound changes in yellow fever infection, characterized by the appearance of large mononuclear or histiocytic cells and the disappearance of small lymphocytes.

### Hypotension and Shock

Infection of the endothelium may play a central role in the pathogenesis of many hemorrhagic fevers. In dengue, infected endothelial cells release large amounts of proinflammatory cytokines (IL-6 and IL-8) and oxygen free radicals that trigger coagulation, fibrinolysis, plasma leakage, and hypotension. Endothelial infection and injury have not been specifically studied in yellow fever, but it is likely that these are important factors in pathogenesis.

### Encephalopathy

In the terminal stage of infection, humans and nonhuman primates develop stupor and coma, which is probably metabolic in origin. Contributing factors include hypoglycemia (due to the liver's impaired gluconeogenesis), decreased perfusion, and acidosis. Changes in tissue concentrations of water and electrolytes in various compartments of the CNS have been described, including intracellular dehydration of medulla, cerebellum, and spinal cord. In addition, the encephalopathy appears to be partially due to the hepatorenal syndrome that frequently accompanies fatal cases of yellow fever. CNS invasion by yellow fever virus is rare. Even in fatal cases, in which seizures and coma are present, inflammatory changes in the brain are not seen.

### Innate Immunity

Although there are few yellow fever-specific studies, it is assumed that the first line of host defense is a nonspecific, innate immune response. This includes the natural killer cell response and other resistance factors that interfere with virus replication before the appearance of virus-specific cytotoxic T cells and antibodies. Many studies of dengue show the importance of type-1 interferons (IFNs) in this nonspecific, innate immune response to flavivirus infection. IFN activates several host defense mechanisms, including increasing natural killer (NK) cells, CD14-bearing monocyte/macrophages, major histocompatibility complex class I (MHC-I) proteins on the host cell surface, Th1-dependent immunoglobulin synthesis, and cytotoxic T-lymphocyte activity.<sup>39–41</sup> Monkeys treated with IFN had lower yellow fever viremia and liver injury,<sup>42</sup> and IFN knockout mice showed poor yellow fever viral clearance and a poor cellular inflammatory response after intracerebral inoculation compared to parental mice.<sup>43</sup> It is uncertain whether these effects were due to a direct antiviral effect, immunomodulation by IFN, or induction of other cytokines. In addition to IFN, a variety of other proinflammatory cytokines and markers of T-cell activation have been found during the viremic period after yellow fever vaccination in humans, including TNF, IL-1, neopterin,  $\beta_2$ -microglobulin, and circulating CD8+ T cells.<sup>44,45</sup> It is likely that similar responses occur in people infected with wild-type yellow fever virus.

The genetic constitution of the host is one of the most important factors influencing the outcome of viral infection. This has been investigated using inbred strains of mice that differed in their resistance to flaviviruses including yellow fever virus.<sup>46</sup> In some cases, resistant mice appeared to be more susceptible to the antiviral action of IFN, although at least one resistance gene (*flv*) confers flavivirus-specific resistance by an IFN-independent mechanism.<sup>47</sup> In general, susceptibility to disease correlated with increased levels of viral replication in tissues. IFN-dependent activation of 2',5'-oligoadenylate synthetase is under genetic control and determines susceptibility to flavivirus infections in mice. It is uncertain whether this mechanism contributes to the severe AEFI with yellow fever 17D.

Since approximately 10% of infected people develop classic yellow fever, it is clear that the innate immune system or other mechanisms may fail to protect the host. This may be due to viral mechanisms that reduce immune clearance by NK cells. Unlike many viruses that decrease the density of MHC-I proteins on the infected cell surface, flaviviruses increase their density through the increased supply of related peptides to the ER through the action of IFN.<sup>48</sup> Since MHC-I proteins protect cells against attack by NK cells, flavivirus-infected cells avoid clearance by the innate activity of NK cells.

### Adaptive Immune Response

Up to 10<sup>4</sup> yellow fever virions are inoculated into extravascular tissues during probing by an infected female mosquito. In an immune host, virus first encounters yellow fever virus-specific neutralizing antibodies in the extracellular transudate and lymph. It is believed that most virions are neutralized, but it is unclear if the entire inoculum is neutralized or whether some portion is processed in the dendritic cell as in the nonimmune host.<sup>37,49</sup> Assuming that yellow fever virus is processed like dengue and other flaviviruses, non-neutralized virus infects epidermal dendritic cells and undergoes replication ("productive infection").

The nonspecific, innate immune response is followed by a specific immune response characterized by the development of neutralizing antibodies and cytotoxic T cells. In addition, cytolytic antibodies against viral proteins on the surface of infected cells and antibody-dependent, cell-mediated cytotoxicity contribute to viral clearance. The humoral response to yellow fever virus is characterized by the appearance of IgM antibodies in the first 7 or 8 days following infection (i.e., 4 or 5 days after illness onset). IgM levels peak 7 to 14 days after illness onset and decline rapidly over 30 to 60 days but may persist for years at low levels. Neutralizing antibodies persist for many years, if not lifelong, after natural yellow fever infection and provide complete protection against disease on reexposure to the virus. No documented case of a second clinical yellow fever infection has been reported. Complement-fixing (CF) antibodies against NS1 expressed on the infected cell surface lead to complement-mediated cytolysis and clearance of infected cells early in recovery. It is not known whether this anti-NS1 CF antibody protects against reinfection or only plays a role in virus clearance during recovery from infection.

People with pre-existing antibody to other flaviviruses (i.e., heterologous antibody) develop broadly cross-reactive

antibody responses following yellow fever virus infection. In contrast to dengue, in which such heterologous antibody may enhance disease, this antibody protects against yellow fever. Nonhuman primates actively immunized with Zika, Wesselsbron, or dengue viruses are protected against a subsequent yellow fever virus challenge.<sup>50,51</sup> Other studies show that humans with broadly reactive antibody to unspecified African flaviviruses have a lower incidence of yellow fever disease than people with primary yellow fever infections.<sup>52</sup>

Although little is known about the human cellular immune responses to yellow fever, it is likely that cytotoxic T lymphocytes kill flavivirus-infected cells and contribute to viral clearance and recovery from primary infection. In studies of yellow fever viral encephalitis in T and B cell knockout mice, CD4+ cells are important for protection.<sup>43</sup> There are no data on human cellular responses to wild-type yellow fever virus.

## DIAGNOSIS

The differential diagnosis of classic yellow fever includes severe malaria with rapid hemolysis, severe hepatitis E in pregnancy, hepatitis D superinfection, other viral hemorrhagic fevers that may rarely have jaundice (e.g., dengue hemorrhagic fever and Crimean–Congo hemorrhagic fever), leptospirosis, and relapsing fever due to *Borrelia recurrentis*. Most hemorrhagic fever viruses, such as Marburg, Ebola, and Lassa fever viruses, are not usually associated with jaundice but may still cause diagnostic confusion. Milder clinical cases or people in the early, anicteric phase of yellow fever resemble people with many other febrile illnesses.

Specific laboratory diagnosis relies on serology or, during the early, anicteric phase, on detection of virus, viral antigens, or viral RNA in blood. None of these methods are commercially available. In clinical samples, yellow fever virus-specific real-time quantitative reverse transcriptase polymerase chain reaction (rtPCR) assays can detect titers as low as 0.1 PFU/mL and much lower than standard rtPCR (lower limit, 1 PFU/mL) or virus isolation in cell culture (lower limit, 10 PFU/mL).<sup>53</sup> In addition to increased sensitivity, both PCR methods give a definitive result in a much shorter time than virus isolation in any system. Because clinical suspicion of yellow fever is low during the early, anicteric phase of infection when viremia is present, isolation, genomic amplification, and antigen detection have played a minor role in yellow fever diagnosis to date.

Serology is the most important diagnostic test, and yellow fever virus-specific IgM enzyme-linked immunosorbent assay (ELISA) is the most widely used serological method. The presence of IgM antibodies in a single serum sample taken on or after day 7 of clinical illness or during the early recovery phase provides a presumptive diagnosis, and demonstration of a fourfold increase in antibody titer in paired sera (using ELISA, neutralization, or HI assays) is confirmatory. The specificity of IgM ELISA is high in primary infections and in most secondary flavivirus infection. Despite this high specificity, cross-reactions between yellow fever and other flaviviruses frequently complicate serological diagnosis, especially in people who live in areas where other flaviviruses are endemic, and confirmation by the more specific neutralization assays may be necessary. When testing a person with the signs and symptoms of yellow fever during a documented yellow fever outbreak, confirmation should not be necessary.

In fatal cases, the characteristic histopathologic liver changes (e.g., midzonal necrosis and Councilman's bodies) are diagnostic. IHC with poly- or monoclonal antibodies to yellow fever virus to detect yellow fever antigen in tissue is diagnostic and more specific than standard histopathology. Despite the high potential for a specific diagnosis, liver biopsies in living patients should not be performed because fatal hemorrhage may occur.

## TREATMENT AND PROGNOSIS

The management of patients with yellow fever has not been optimized because disease occurs in areas with rudimentary medical services and the hemodynamic instability of these patients often precludes transport. Because there is no yellow fever virus-specific therapy, intensive supportive care to maximize tissue perfusion, reduce hemorrhagic complications, maintain adequate glucose levels, and provide nutritional maintenance is necessary to reduce the mortality of yellow fever. In addition, the following has been recommended: nasogastric suction to prevent gastric distension and aspiration, intravenous agents to reduce gastric acidity and prevent gastric bleeding, fluid replacement with normal saline or Ringer's lactate, vasopressors if needed, administration of oxygen, correction of metabolic acidosis, treatment of bleeding with fresh-frozen plasma, and treatment of secondary infections with antibiotics. Unfortunately, patients with yellow fever do not respond dramatically to fluid replacement or vasopressors; this is likely due to irreversible pathophysiologic processes and the unchecked effect of TNF or other cytokines.<sup>36</sup> Heparin should only be used to treat DIC when there has been documented consumption of clotting factors and activation of fibrinolytic mechanisms and when there is adequate laboratory support to monitor heparin's effects. If available and needed, dialysis should be used in cases of renal failure or anuria. Other medical considerations may include orthotopic liver transplantation or the use of extracorporeal support systems.<sup>54</sup> Although these are beyond the capacity of developing nations, they may be potential interventions for Western travelers who develop yellow fever following travel or who develop MOSF as an adverse effect after yellow fever immunization. In the future, other possible nonspecific treatments may include anticytokine therapies or cytokine receptor blockers to prevent cell apoptosis.

There is no specific antiviral treatment. Although ribavirin has activity against yellow fever virus at high (potentially cytotoxic) concentrations in vitro,<sup>55</sup> ribavirin monotherapy has failed in animal studies. Passive antibody, IFN, and IFN inducers are only effective if given before infection or during incubation. There is no current indication for their use, and passive antibody protection should only be considered in the setting of postexposure prophylaxis (i.e., after known infection and before illness onset), such as in a laboratory exposure. Corticosteroids have not been evaluated for the treatment of yellow fever.

## PREVENTION AND CONTROL

### Yellow Fever Vaccine

During the 1930s, both wild-type yellow fever virus strains, Asibi and French, were attenuated to derive live

vaccines known as 17D and the French neurotropic vaccine, respectively.<sup>56</sup> Currently, 17D is the only strain of yellow fever virus used for vaccination. During vaccine production from 1937 to 1941, two different 17D substrains, 17D-204 and 17-DD, were developed in parallel; these are used for current vaccine production. Although they differ with respect to 17D substrain and other production qualities, they are both produced in embryonated eggs and meet the same WHO standards for safety and potency. In addition, their biologic performance is similar with respect to seroconversion rate, quality of the immune response, durability of immunity, safety, and tolerability. 17D vaccines are a heterogeneous mixtures of multiple virus subpopulations. Not surprisingly, differences have been found in plaque size, oligonucleotide fingerprints, and nucleotide sequencing. There is no evidence that such variations affect safety or efficacy.

Three manufacturers in Brazil, France, and Senegal produce vaccine for the Expanded Programme of Immunization (EPI) and mass vaccination campaigns. Sanofi Pasteur and Evans (a Chiron affiliate) export vaccine for the traveler's market. Approximately 55 million doses are produced annually by these sources.

### Immune Response

More than 95% of vaccinated people develop neutralizing antibodies within 10 to 14 days of immunization. Race does not appear to influence response rates. In one study, males had lower antibody titers than females.<sup>57</sup> In the majority of cases, antibody titers following vaccination are lower, and their appearance is delayed compared to natural yellow fever virus infections. This is likely due to less virus replication and antigen expression by the 17D strain. The minimal protective level of neutralizing antibodies induced by 17D vaccine has been estimated by dose-response studies in rhesus monkeys that are subsequently challenged after immunization with virulent yellow fever virus. In such studies, log neutralization index<sup>58</sup> (LNI; measured by plaque reduction) of 0.7 or greater measured 20 weeks after immunization was strongly associated with protection. Human clinical trials of 17D vaccine have shown geometric mean LNI values of 2.1 or greater measured within 1 month after vaccination.<sup>57</sup> The International Health Regulations stipulate that the vaccination certificate for yellow fever is valid 10 days after administration of 17D vaccine, corresponding to the time at which the majority of vaccinees are demonstrably immune. Immunity following 17D vaccination is remarkably durable and may be lifelong. Although the yellow fever immunization certificate for international travel is valid for 10 years, this interval was based on published studies showing that neutralizing antibodies were present in more than 90% of people 16 to 19 years after vaccination. Later studies of U.S. military veterans from World War II tested 30 to 35 years after a single dose of 17D vaccine showed that slightly more than 80% had neutralizing antibody, and in some subgroups more than 95% had it.<sup>56</sup>

### Adventitious Viruses

In 1966, yellow fever 17D vaccines were found to be contaminated with avian leukosis virus (ALV), a retrovirus with a high prevalence in chicken embryos. New ALV-free seeds were prepared in the 1970s, and all international

manufacturers now use ALV-free seeds as stipulated by WHO. WHO still permits some local manufacturers to use ALV-contaminated embryos. Although the presence of ALV in yellow fever vaccine is undesirable because of the possible insertion of ALV oncogenes, there is no evidence to implicate ALV in human disease. This was addressed in a retrospective study of cancer deaths in World War II veterans in which the incidence of all cancers, lymphoma, and leukemia was not significantly different in people vaccinated 5 to 22 years previously with 17D vaccine than in those not vaccinated.

During the original formulation and early use of 17D vaccines, pooled human serum was used as a vaccine stabilizer. This resulted in vaccine contamination with hepatitis B virus and a massive outbreak of jaundice and hepatitis in yellow fever vaccine recipients. Human serum was eliminated from yellow fever vaccines by 1942, and current vaccines are not contaminated with human hepatitis viruses.

### Vaccine Dose, Route of Administration, and Preparations

A 17D vaccine dose contains approximately  $10^5$  PFU in 0.5 mL and is given subcutaneously, usually in the upper arm. All yellow fever vaccines are prepared as lyophilized powder but vary with respect to stabilizer additives and salt content. Some contain sodium chloride and buffer salts and are reconstituted with sterile water, whereas others are reconstituted with saline. Because there is no preservative in the vaccine and because the vaccine rapidly loses potency after reconstitution, it must be refrigerated at the point of use and held on ice and used soon after reconstitution. In the United States, reconstituted vaccine must be discarded within 1 hour; in EPI systems, it must be discarded within 4 hours. Vaccine is supplied in single- and multiple-dose containers. Although combination vaccines have been tested clinically (e.g., yellow fever-measles and yellow fever-typhoid), no such products are available.

### Viremia Following 17D Vaccination

Wild-type yellow fever virus causes higher viremia than the 17D vaccine strains in monkeys and humans. Most adult vaccinees have virus titers less than 100 PFU/mL, which is far below the 4 or 5 logs of virus titer needed to infect mosquitoes. The low viremia following 17D vaccine may explain the apparent low risk of transplacental transmission in women immunized during pregnancy. Viremia begins 3 or 4 days after vaccination and lasts 1 to 3 days.<sup>56</sup> Thus, the incubation period and duration of viremia are similar to those of wild-type yellow fever virus. Like naturally acquired infections, viremia disappears when neutralizing antibodies develop 8 or 9 days after immunization. There are no data on viremia levels in infants or children given 17D vaccine or in people who are immunosuppressed.

### Genetic Stability during Replication in the Vaccinated Host

The 17D vaccine is not clonal. It is a heterogeneous mixture of virus variants with varying antigenic, genetic, and biological properties. Despite this, it is considered one of the safest vaccines in use today and thought to have very little

potential for reversion to wild-type or emergence of pathogenic strains. Isolation of a strain that was more virulent than the parental 17D vaccine strain has been documented only once following routine vaccination. In one fatal human encephalitis case, the viral isolate from the brain had higher neurovirulence in mice than the 17D-204 strain. This isolate caused encephalitis in nonhuman primates, reacted with a wild-type virus-specific monoclonal antibody, and had two amino acid changes in the E protein and one in NS4B. Other studies indicate a high degree of genetic stability of 17D virus during *in vivo* replication. Vaccine virus strains isolated from the sera of people vaccinated with the 17D-204 vaccine contained no mutations in the structural genes and a few mutations in the nonstructural protein genes, especially the NS5 protein gene.<sup>59</sup> Other studies have supported the finding that mutations in yellow fever virus tend to accumulate at a significantly lower rate than expected for an RNA virus.<sup>16</sup>

### Revaccination

Revaccination or vaccination of people with naturally acquired immunity is followed by a booster antibody response in most vaccinees, although the rise in titer is less than that seen in primary vaccination. This suggests that there is decreased virus replication due to the pre-existing immunity. A stronger antibody response following revaccination is more likely in individuals with a low neutralizing antibody titer prior to vaccination. The response is characterized by a large and rapid increase in IgG antibodies, indicating a memory response resulting from prior sensitization.

### Immunization in People with Prior Flavivirus Immunity

Because of cross-reactive antigenic determinants, the primary immune response to 17D vaccine may be qualitatively different in people with preexisting heterologous immunity. Several studies have shown that naturally acquired dengue immunity reduces seroconversion and blunts the immune response to 17D vaccine, whereas preexisting immunity to flaviviruses in the Japanese encephalitis complex does not. There is no clear evidence that prior flavivirus immunity enhances replication of yellow fever 17D virus or the immune response to 17D virus.

Similarly, people with preexisting immunity to the yellow fever 17D vaccine have a qualitatively different immune response to immunization with vaccines against heterologous flaviviruses. In yellow fever-immune individuals, vaccinated with an experimental, attenuated dengue vaccine, the antibody response was greater in magnitude and duration than in nonimmune individuals, suggesting that cross-reactive antibodies may be associated with enhanced dengue virus replication *in vivo*. A different mechanism, the anamnestic responses to cross-reactive determinants, explains the higher response in recipients of inactivated vaccines (e.g., tick-borne encephalitis vaccine).

People with heterologous flavivirus immunity broadly respond to 17D vaccination with both homologous and heterologous neutralizing antibodies. The phenomenon of "original antigenic sin" has been noted in people previously vaccinated with 17D virus and subsequently infected with

another flavivirus. In such cases, an anamnestic response leads to a rapid rise in yellow fever antibodies, but the antibody response to the more recent heterologous infection is delayed and diminished. This phenomenon may lead to diagnostic confusion in patients with clinical syndromes resembling naturally acquired yellow fever.

### Yellow Fever Vaccine Efficacy in Humans

The efficacy of yellow fever vaccine has never been tested in controlled human clinical trials. Numerous studies in nonhuman primates have demonstrated that vaccination protects vaccine recipients and that protection is strongly correlated with the development and titers of neutralizing antibody. The importance of neutralizing antibody has been shown by the protection of animals by passive immunization (infusion of serum containing yellow fever virus-specific neutralizing antibody) before or soon after challenge with virulent yellow fever virus.

Several primary observations support yellow fever vaccination as being protective in humans, including the reduction of laboratory-associated infections in vaccinated workers; the fact that in Brazil and other South American countries, yellow fever only occurs in unvaccinated people; and the rapid disappearance of cases during campaign-style vaccination programs initiated during epidemics. One of the greater testaments to the effectiveness of yellow fever vaccination is the disappearance of yellow fever from French-speaking West Africa after institution of mandatory yellow fever immunization with the French neurotropic vaccine in the 1940s. High vaccine coverage was followed by a marked reduction in disease despite continued human exposure to the enzootic cycle. Unpublished reports comparing the yellow fever incidence among the vaccinated and unvaccinated populations during a 1986 epidemic in Nigeria estimate the effectiveness to be approximately 85%.<sup>56</sup> Because there is an effective vaccine available that is now considered the standard of care, it is highly unlikely that a placebo-controlled trial of the 17D or any newer yellow fever vaccines will be performed. Given these constraints, licensure of any new yellow fever vaccines would likely have to be granted based on a combination of animal safety data and studies using immunologic surrogates.

### Vaccine Failure

Rarely, healthy people fail to develop neutralizing antibodies following 17D vaccination. This is not an absolute refractoriness; people who fail to develop antibody after their first vaccination may develop antibody upon revaccination. More rarely, a person who was previously vaccinated may develop clinical yellow fever. Although it is uncertain whether all of these people were properly vaccinated with appropriately handled 17D vaccine, there have been five reports of vaccine recipients who developed yellow fever since development of the yellow fever vaccine.<sup>56</sup>

Three host factors (malnutrition, HIV infection, and pregnancy) have been associated with failure to respond immunologically to 17D vaccine. Further studies are required to assess the relevance of these findings to the use of 17D vaccine in EPI in Africa, particularly where these conditions may frequently result in vaccine failure. In one study, only approximately 40% of pregnant women seroconverted after vaccination

compared to 82% to 94% among nonpregnant females of childbearing age, male students, and the general population. This difference was attributed to the immunosuppression associated with pregnancy and emphasizes the need to reim-munize at-risk women who were inadvertently vaccinated during pregnancy.

HIV infection has been associated with a reduced immunologic response to a number of inactivated and live, attenuated vaccines. Some case reports have suggested that vaccinating HIV-infected people without immunosuppression results in seroconversion. However, when 17D vaccine was administered to a small number of adult, HIV-infected travelers with CD4+ counts of 200 or more cells/ $\mu$ L, only 70% seroconverted within 1 month of vaccination.<sup>56</sup> Among HIV-infected infants in developing nations, only 17% developed neutralizing antibodies within 10 months of 17D vaccination compared to 74% of HIV-uninfected controls matched for age and nutritional status.<sup>33</sup> The mechanisms for this diminished response are uncertain. Although an encephalitis case has been reported in an HIV-infected Thai man following yellow fever vaccination, the number of HIV-infected people vaccinated with 17D vaccine is too small to assess safety.<sup>34</sup>

### Yellow Fever Vaccine Safety

Preventing infection by vaccination or reducing the abundance of *Ae. aegypti* are the only two effective strategies to reduce yellow fever morbidity and mortality. 17D vaccine, the currently approved yellow fever vaccine, has been available since 1937 and widely used during outbreaks in Africa and South America and by the military and travelers operating in or visiting endemic countries.<sup>49,60</sup> In many affected countries, the need for yellow fever vaccination remains and, in fact, may be increasing.<sup>19,20,61</sup> Because of the vaccine's safety profile, its effectiveness in preventing yellow fever, the lack of virus-specific treatment, and the high mortality of yellow fever, vaccination is an integral strategy for preventing yellow fever-associated mortality and morbidity. In addition, travelers to areas where yellow fever is zoonotic, endemic, or epidemic should be vaccinated if they are at increased risk for infection based on their daily activities or living conditions.<sup>60,62,63</sup>

### General Adverse Events

Reactions to 17D yellow fever vaccine are typically mild. After vaccination, vaccinees often report mild headaches, myalgia, low-grade fevers, or other minor symptoms for 5 to 10 days. Reactogenicity of 17D vaccine has been monitored in 12 clinical trials conducted from 1953 to 2002. In trials in which vaccinees were actively followed, incidence rates of 18% to 50% were detected. In one large study, the most common systemic side effects (which did not differ across treatment groups) were headache (~33% of subjects), myalgia (~25%), malaise (~19%), fever (~15%), and chills (~11%).<sup>57</sup> These were generally mild, and few vaccinees curtailed their regular activities. No placebo controls were included in these trials, making interpretation of causality of the AEFIs difficult. Immediate hypersensitivity reactions, characterized by rash, urticaria, or asthma, occur principally among people with histories of allergies to egg or other substances and are estimated to occur in 1 out of 131,000 vaccinations.<sup>64</sup>

Gelatin, used as a stabilizer in yellow fever vaccine, has been implicated as a cause of allergic reactions to other vaccines and may play a role in reactions to yellow fever vaccine.

### Yellow Fever Vaccine-Associated Viscerotropic Disease

Increasingly frequent reports of yellow fever vaccine-associated viscerotropic disease (YEL-AVD), a syndrome of MOSF following 17D vaccination that pathologically and clinically resembles naturally acquired yellow fever, have raised concern about the safety of this vaccine.<sup>65,68</sup> A total of 29 cases of YEL-AVD have been reported internationally.

From 1996 through 2004, the CDC received reports of 11 recipients of 17D-204 vaccine who developed this newly recognized syndrome in the United States (M. Russell, personal communication, 2005).<sup>62,65,67,68</sup> Ten of these cases were in civilians vaccinated in anticipation of travel, and one was in the military. All 11 people (median age, 64 years; range, 22 to 79 years) became ill within 2 to 5 days of vaccination and developed MOSF requiring intensive care; six died (case fatality rate, 55%).<sup>67,68</sup> In addition to fever, hypotension, and respiratory failure, these people had markedly elevated hepatocellular enzymes and bilirubin, lymphocytopenia, and thrombocytopenia. Vaccine-type yellow fever virus was isolated from the blood of two people on the seventh and eighth days after vaccination. Using IHC, yellow fever antigen was identified in the liver in one person and in multiple tissues (including lung, lymph node, spleen, heart, liver, and muscle) in two fatal cases. Two people with YEL-AVD also had evidence of neuroinvasive infection.

In addition to the 11 U.S. cases, 18 international cases of YEL-AVD have been reported in the literature, at scientific meetings, or to vaccine manufacturers.<sup>62,66–70</sup> The first three international cases from Australia and Brazil were reported simultaneously with the first U.S. cases. They were clinically similar to the U.S. cases except that younger people were affected. In these cases, histopathologic changes characteristic of wild-type yellow fever were noted in the liver. Using IHC and electron microscopy, yellow fever antigen and flavivirus-like particles were found to be present in the areas of mid-zonal necrosis. Vaccine-type virus was isolated from all three people. The isolated viruses retained their vaccine phenotype when placed into experimental animals. No genomic changes previously associated with reversion to virulence were detected. Within months of these reports, other cases of hospitalized people with fever, elevated hepatocellular enzymes, and renal abnormalities were identified, suggesting that, like naturally acquired infections, there may be a spectrum of AEFI.<sup>69,71,72</sup> These international cases occurred among recipients of 17D-204 and 17DD vaccine.

All but of these 29 cases of YEL-AVD have occurred since 1996.<sup>68</sup> One case occurred in 1975 and was identified retrospectively in Brazil. It is not known whether additional cases occurred between 1975 and 1996 but were unrecognized or whether YEL-AVD has newly emerged. No comparable cases were identified in a retrospective review of VAERS reports from 1990 to 1996 (M. Cetron, personal communication, 2004). The true incidence of YEL-AVD is also unknown, but attempts to quantify the risk and identify risk factors continue.<sup>67,68,73</sup>

## Yellow Fever Vaccine–Associated Neurotropic Disease

The 17D strain of yellow fever virus has retained some of its neurovirulence as demonstrated by intracerebral inoculation of mice and nonhuman primates. In the first decade of vaccine use, vaccine-associated neurotropic disease (postvaccinal encephalitis), primarily among infants, was the most common serious AEFI. From 1945 through 1991, 21 well-documented cases were reported worldwide. Of these, 16 (76%) occurred in infants aged 9 months or younger.<sup>56</sup> Estimates of the yellow fever vaccine-associated neurotropic disease (YEL-AND) rate among children aged 12 months or younger were elevated and ranged from 0.5 to 4 per 1000 doses. As a result, it was recommended that vaccinating infants younger than 9 months old should be avoided because of the encephalitis risk.<sup>62</sup> A decision to administer vaccine to infants younger than 9 months of age should be based on the risk of exposure to natural infection, but the vaccine should not be administered to infants aged 6 months or younger. The only YEL-AND case in the United States from 1945 to 1991 involved a 3-year-old child who died in 1965.<sup>74</sup>

From the mid-1990s through the mid-2000s, unlike earlier reports, most reported cases of YEL-AND have occurred in adults. In a retrospective review of VAERS data from 1990 to 2002 and through prospective investigation of suspected cases of YEL-AND from 2000 to 2004 reported to VAERS, a total of 15 cases of YEL-AND have been identified among U.S. citizens.<sup>68</sup> The first four were reported and prospectively investigated in 2001 and 2002.<sup>75</sup> A retrospective review of 1995 to 2002 VAERS data identified four more people; all developed Guillain-Barré (GBS) syndrome following vaccination. Since 2002, seven more cases have been prospectively identified among U.S. residents; four had acute demyelinating disease; two had GBS; and one had encephalitis (M. Russell, CDC, personal communication 2005). Like all YEL-AVD cases, all 15 of these people became ill after their first yellow fever vaccination. In addition to these U.S. cases, five international cases have been reported to vaccine manufacturers from 1991 through 2001.<sup>34,73</sup> Of these, three were cases of encephalitis (including one fatal case); one was a case of GBS and one was a case of bulbar palsy. In one series the YEL-AND incidence was estimated to be 3.3 per 1 million doses.

In children, YEL-AND was characterized by the onset of fever and seizures, obtundation, meningismus, and paresis 7 to 21 days after immunization. In adults, symptoms included severe headache, confusion, and aphasia. Illness onset in adults varied from 4 to 23 days postvaccination, was similar to that in children, and was longer than that seen with YEL-AVD.<sup>75</sup> In both groups, CSF contains up to 500 cells/ $\mu$ L (predominantly lymphocytic) and elevated protein.

The clinical course is generally brief, recovery is complete, and mortality is low. Of the 15 reported U.S. civilians who developed YEL-AND from 1992 to 2003, all were hospitalized but none died. Similarly, of 21 people who developed YEL-AND from 1945 through 1991, only 1 (5%) died; none of the 16 infants aged 9 months or younger died.<sup>56</sup> Although the risk of death is believed to be low with this syndrome, certain groups of vaccine recipients may be at greater risk of death. In 2002, a fatal case of YEL-AND involving a 53-year-old man with previously unrecognized HIV infection was reported in Thailand.<sup>34</sup>

## Risk Factors for YEL-AVD and YEL-AND

Two passive reporting surveillance systems have been used to estimate the frequency of these events: VAERS and a manufacturer's postmarketing safety surveillance system.<sup>67,71,76</sup> Increasing age is a risk factor for serious AEFI. Analyses of 1990 to 2003 VAERS data have demonstrated that people aged 60 years or older are at increased risk for both YEL-AVD and YEL-AND.<sup>67,76</sup> During this period, the all-ages incidence for YEL-AVD in the United States was estimated to be four cases per 1 million civilian doses sold. For vaccine recipients aged 61 to 70 years and those aged 71 years or older, the incidence was 23 and 19 cases per 1 million doses sold, respectively. Using these same data, the all-ages incidence for YEL-AND was estimated to be five cases per 1 million civilian doses sold. For vaccine recipients aged 61 to 70 years and those aged 71 years or older, the reported incidence was 18 and 19 cases per 1 million doses sold, respectively.

## Thymus Disease as a Risk Factor

Although not as defined as age, it appears that removal of the thymus or conditions associated with thymomas are risk factors for YEL-AVD. Of 29 people with YEL-AVD identified worldwide through 2003, 4 (14%) had undergone thymectomy 2 to 20 years prior to receiving yellow fever vaccination.<sup>68</sup> Because the incidence of thymomas is low,<sup>77</sup> this observation suggests that a history of thymectomy or conditions associated with thymomas (e.g., myasthenia gravis and hypogammaglobulinemia) may be risk factors for YEL-AVD. Thymomas have been associated with decreased antibody levels, abnormal T-lymphocyte maturation, and several autoimmune conditions.

## Risk Assessment

The specific mechanisms underlying serious AEFI after yellow fever vaccination are unknown. As a result, defining at-risk groups whose risk from vaccination is greater than their benefit is difficult. Notably, all reported YEL-AVD and YEL-AND cases occurred in people who were receiving their first yellow fever vaccination. No such cases of people receiving a booster dose have been reported. People receiving booster doses may have lower levels of viremia, significant differences in cytokine response, or a more profound neutralizing antibody response to check viral proliferation compared to primary recipients.

Increasing age, thymoma, and primary vaccination account for some of the increased number of cases; systematic changes in vaccine administration should also be considered. For example, before 1996, immune serum globulin (ISG) was often given as part of travel immunizations to reduce the risk of hepatitis A. Laboratory studies have shown that ISG used in the United States contains significant titers of neutralizing antibody to yellow fever due to the number of plasma donors previously vaccinated while in the military. Whether introduction of hepatitis A vaccine in 1996, which eliminated the need for ISG, may have inadvertently reduced the number of vaccinees receiving passive antibody protection is unknown.

Yellow fever vaccine has been considered one of the safest live-virus vaccines. Reports of serious AEFI after 17D vaccination require reassessment of vaccine use among travelers,

and possibly among residents of endemic areas.<sup>49</sup> Yellow fever remains a serious and potentially fatal disease without an efficacious treatment. As a result, the need to vaccinate travelers and residents of endemic areas remains. Categorically refusing an older person vaccine on the basis of age without assessing his or her true risk for disease is not acceptable. Still, the association of increased AEFI risk with age emphasizes the importance of carefully screening travel itineraries of older travelers, travelers with a history of thymoma, or first-time vaccine recipients and only vaccinating those traveling in yellow fever-endemic areas. For travelers whose risk of serious AEFI is great and administration of vaccine is not considered an option, alternative means of prevention, such as personal protection (e.g., use of insect repellants containing *N,N*-diethyl-meta-toluamide or permethrins, wearing long sleeves and pants, using bed nets at night, or staying in air-conditioned or well-screened quarters) may be considered.

### Vaccine-Associated Adverse Events in Persons Infected with HIV

Yellow fever is endemic across sub-Saharan Africa, where there is a high prevalence of HIV infection. This region has been the site of numerous vaccination campaigns to control yellow fever epidemics. During emergency vaccination campaigns, AEFI surveillance was established in Kenya in 1993 (passive surveillance) and in Cote d'Ivoire in 2001 (active surveillance.) (D. Gubler, personal communication, 2002). Surveillance was population based and not restricted to case investigations among HIV-infected people. Four encephalitis cases (only one of which was an HIV-infected person) were identified in Kenya,<sup>56</sup> and none were identified in Cote d'Ivoire; no cases of viscerotropic disease were identified during either vaccine campaign. Further studies (e.g., cohort studies of HIV-infected people and case-control studies of the general population) and AEFI surveillance during campaigns in countries with high HIV prevalence are needed to define the risk of serious AEFI in HIV-infected people.

### CONCLUSIONS

Yellow fever remains a major public health concern in sub-Saharan Africa and tropical South America despite the availability of an effective vaccine that can have tremendous impact on disease control. Because yellow fever is an epizootic disease, the potential for human outbreaks will always remain when vaccination programs are not maintained. Unfortunately, efforts to control disease have decreased, and proposals to integrate yellow fever vaccine into EPI and routine vaccination activities have been largely replaced by a policy of emergency vaccination campaigns after an outbreak is identified.

Despite the restricted range of endemic virus transmission, it is important for all physicians to be aware of the clinical manifestations and epidemiology of yellow fever because of its potential to cause large urban outbreaks in areas outside of South America and Africa, because of the risk of travelers to these endemic areas, and because of serious adverse events associated with yellow fever vaccination. Because air travel enables anicteric, viremic travelers to return to their homes from any area of the world in less than 24 hours and because of the possibility that the

traveler's home has a potential mosquito vector, there is potential for large urban outbreaks of human disease in new areas.

# Dengue and Dengue Hemorrhagic Fever

DUANE J. GUBLER

## INTRODUCTION

The first reports of major epidemics of an illness thought to possibly be dengue occurred on three continents (Asia, Africa, and North America) in 1779 and 1780.<sup>1-4</sup> However, reports of illnesses compatible with dengue fever occurred even earlier. The earliest record found to date was in a Chinese “encyclopedia of disease symptoms and remedies,” first published during the Chin Dynasty (265 to 420 AD) and formally edited in 610 AD (Tang Dynasty) and again in 992 AD during the Northern Sung Dynasty.<sup>5</sup> The disease was called “water poison” by the Chinese and was thought to be somehow connected with flying insects associated with water. Outbreaks of illness in the French West Indies in 1635 and in Panama in 1699 could also have been dengue.<sup>4,6</sup> Thus, dengue or a very similar illness had a wide geographic distribution before the 18th century, when the first known pandemic of dengue-like illness began. It is uncertain that the epidemics in Batavia (Jakarta), Indonesia, and Cairo, Egypt, in 1779 were dengue.<sup>7</sup>

At some point in the past, probably with the clearing of the forests and development of human settlements, dengue viruses moved out of the jungle and into a rural environment, where they were, and still are, transmitted to humans by peridomestic mosquitoes such as *Aedes albopictus*. Migration of people and commerce ultimately moved the viruses into the villages, towns, and cities of tropical Asia, where the viruses were most likely transmitted sporadically by *Aedes albopictus* and other closely related peridomestic *Stegomyia* species.

The slave trade between West Africa and the Americas and the resulting commerce were responsible for the introduction and the widespread geographic distribution of an African mosquito, *Aedes aegypti*, in the New World during the 17th, 18th, and 19th centuries. This species became highly adapted to humans and urban environments and was spread throughout the tropics of the world by sailing ships. The species first infested port cities and then moved inland as urbanization expanded. Because *Ae. aegypti* had evolved to become intimately associated with humans, preferring to feed on them and to share their dwellings, this species became a very efficient epidemic vector of dengue and yellow fever viruses. Therefore, when these viruses were introduced into port cities infested with *Ae. aegypti*, epidemics occurred. It was in this setting that major pandemics of dengue fever occurred during the 18th, 19th, and early 20th centuries, as the global

shipping industry developed and port cities were urbanized in response to increased commerce and ocean traffic. The last major pandemic began during World War II and continues through the present.<sup>8</sup>

The earliest known use of the word *dengue* to describe an illness was in Spain in 1801.<sup>9</sup> However, the most likely origin of the word is from Swahili.<sup>10,11</sup> In both the 1823 and 1870 epidemics of dengue-like illness in Zanzibar and the East African coast, the disease was called *Ki-Dinga pepo*. From this came the name *dinga* or *denga*, which was used to describe the illness in both epidemics. Christie<sup>10,11</sup> speculates that the name *denga* was taken via the slave trade to the New World, where it was called “Dandy fever” or “The Dandy” in the St. Thomas epidemic of 1827. The illness was first called *dunga* in Cuba during the 1828 epidemic, but later changed to dengue, the name by which it has been known ever since.<sup>12</sup> Most likely, the Spanish recognized the disease in Cuba as the same one that was called dengue in Spain in 1801. If the word *dengue* did originate in East Africa from *dinga* or *denga*, this suggests the disease was occurring before the 1823 epidemics described by Christie. This is not unlikely since epidemics were reported in Africa, the Middle East, and Spain in the late 1700s.

With documentation that yellow fever was transmitted by mosquitoes, many early workers suspected that dengue fever was also mosquito-borne. In the previrology era, work was slow and relied on use of human volunteers. Work done by Graham (1903),<sup>13</sup> Bancroft (1906),<sup>14</sup> and Cleland and colleagues (1918)<sup>15</sup> documented dengue transmission by mosquitoes.

Although it had been shown that dengue fever was caused by a filterable agent,<sup>16,17</sup> the first dengue viruses were not isolated until the 1940s, during World War II.<sup>18-21</sup> Dengue fever was a major cause of morbidity among Allied and Japanese soldiers in the Pacific and Asian theaters. Sabin and his group were able to show that some virus strains from three geographic locations (Hawaii, New Guinea, and India) were antigenically similar.<sup>20,21</sup> This virus was called dengue 1 (DENV-1), and the Hawaii virus was designated as the prototype strain (Haw-DENV-1). Another antigenically distinct virus strain isolated from New Guinea was called dengue 2 (DENV-2), and the New Guinea C strain (NGC-DENV-2) was designated the prototype. The Japanese virus isolated by Kimura and Hotta<sup>18,19</sup> was subsequently shown to be DENV-1 as well. Two more serotypes, dengue 3 (DENV-3) and dengue 4 (DENV-4), were later isolated from patients with a hemorrhagic disease during an epidemic in Manila in 1956.<sup>22</sup> Since these original isolates were made, thousands of dengue viruses have been isolated from all parts of the tropics; all have fit into the four-serotype classification.

The occurrence of severe and fatal hemorrhagic disease associated with dengue infections is not unique to the 20th century. Patients with disease clinically compatible with dengue hemorrhagic fever (DHF) have been reported sporadically since 1780, when such cases were observed in the Philadelphia epidemic.<sup>1</sup> Significant numbers of cases of hemorrhagic disease were associated with several subsequent epidemics, including Charters Towers, Australia, in 1897, Beirut in 1910, Taiwan in 1916, Greece in 1928, and Taiwan in 1931.<sup>23-29</sup> However, epidemic occurrences such as these were relatively rare, and the long intervals between them made each a unique event that was not considered important in terms of a

long-term, continuous public health problem. Understanding the emergence of dengue and DHF as a global public health problem in the last half of the 20th century requires a review of the ecological and demographic changes that occurred in the Asian and American tropics during this period. The detailed history of dengue has been recently reviewed.<sup>30</sup>

## AGENTS

There are four dengue virus serotypes: DENV-1, DENV-2, DENV-3, and DENV-4. They belong to the genus *Flavivirus*, family *Flaviviridae* (of which yellow fever virus is the type species), which contains approximately 70 viruses.<sup>31</sup> The flaviviruses are relatively small (40–50 nm) and spherical with a lipid envelope. The flavivirus genome is approximately 11,000 bases and is made up of three structural and seven nonstructural proteins. There are three major subgroups within this family: tick-borne, mosquito-borne, and viruses with no known arthropod vector. The dengue viruses form a complex within the mosquito-borne subgroup. All flaviviruses have common group epitopes on the envelope protein that result in extensive cross-reactions in serologic tests. These make unequivocal serologic diagnosis of flavivirus infections difficult. This is especially true of the four dengue viruses. Infection with one dengue serotype provides lifelong immunity to that virus, but there is no cross-protective immunity to the other serotypes. Thus, persons living in an endemic area can be infected with three, and probably four, dengue serotypes during their lifetime.

## EPIDEMIOLOGY

### Natural History

Humans are infected with dengue viruses by the bite of an infective *Ae. aegypti* mosquito.<sup>32</sup> *Ae. aegypti* is a small, black-and-white, highly domesticated urban mosquito that prefers to lay its eggs in artificial containers commonly found in and around homes in the tropics, for example, flower vases, old automobile tires, buckets that collect rainwater, and trash in general. Containers used for water storage, especially 55-gallon drums and cement cisterns, are especially important in producing large numbers of adult mosquitoes in close proximity to dwellings where people live and work. The adult mosquitoes prefer to rest indoors, are unobtrusive, and prefer to feed on humans during daylight hours. The female mosquitoes are very nervous feeders, disrupting the feeding process at the slightest movement, only to return to the same or a different person to continue feeding moments later. Because of this behavior, *Ae. aegypti* females will often feed on several persons during a single blood meal and, if infective, may transmit dengue virus to multiple persons in a short period of time even if they only probe without taking blood.<sup>33</sup> It is not uncommon to see several members of the same household become ill with dengue fever within a 24- to 36-hour time frame, suggesting transmission by a single infective mosquito (D.J. Gubler, unpublished data). It is this behavior that makes *Ae. aegypti* such an efficient epidemic vector. Inhabitants of dwellings in the tropics are rarely aware of the presence of this mosquito, making its control difficult.

After a person is bitten by an infective mosquito, the virus undergoes an incubation period of 3 to 14 days (average, 4 to

7 days), after which the person may experience acute onset of fever accompanied by a variety of nonspecific signs and symptoms. During this acute febrile period, which may be as short as 2 days and as long as 10 days, dengue viruses may circulate in the peripheral blood. If other *Ae. aegypti* mosquitoes bite the ill person during this febrile viremic stage, those mosquitoes may become infected and subsequently transmit the virus to other uninfected persons, after an extrinsic incubation period of 8 to 12 days.<sup>32</sup>

### Changing Disease Patterns

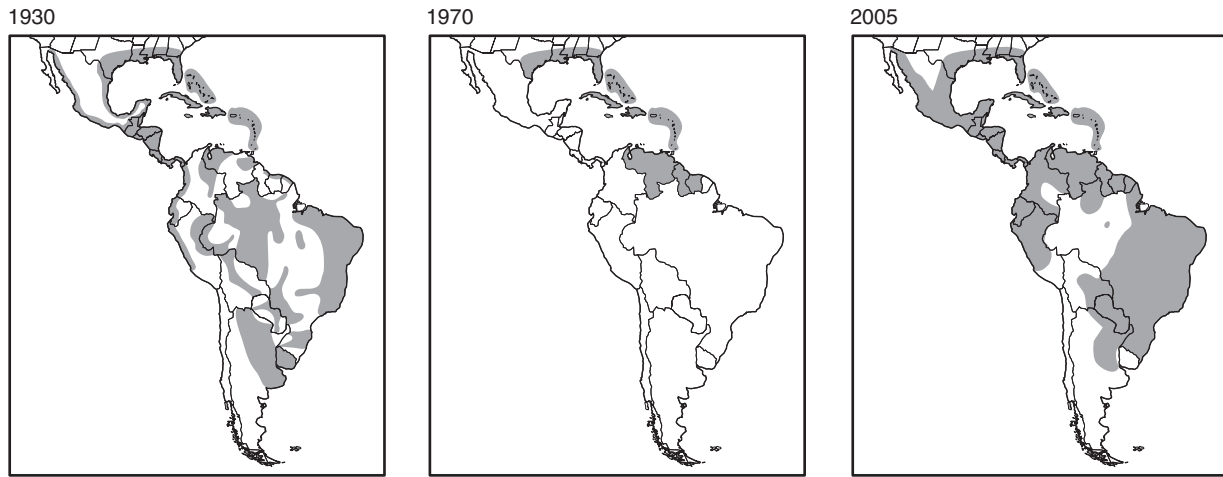

The disease pattern associated with dengue, which was characterized by relatively infrequent epidemics until the 1940s, changed with the ecological disruptions in Southeast Asia during and after World War II. Ideal conditions for increased transmission of mosquito-borne diseases were created, and in this setting a global pandemic of dengue began. With increased epidemic transmission, hyperendemicity (the cocirculation of multiple dengue virus serotypes) developed in Southeast Asian cities, and epidemic DHF, a newly described disease, emerged.<sup>34,35</sup> The first known epidemic of DHF occurred in Manila, in 1953–1954, but within 20 years the disease had spread throughout Southeast Asia. By the mid-1970s, DHF had become a leading cause of hospitalization and death among children in the region.<sup>36</sup> In the 1980s and 1990s, dengue transmission in Asia further intensified; epidemic DHF increased in incidence and expanded geographically west into India, Pakistan, Sri Lanka, and the Maldives, and east into China.<sup>34,35</sup> At the same time, the geographic distribution of epidemic DHF was expanding into new regions—the Pacific islands in the 1970s and 1980s and the American tropics in the 1980s and 1990s.<sup>8,34,35,37–42</sup>

Epidemiologic changes in the Americas have been the most dramatic. In the 1960s and most of the 1970s, epidemic dengue was rare in the American region because the principal mosquito vector, *Ae. aegypti*, had been eradicated from most of Central and South America.<sup>41,42</sup> The eradication program was discontinued in the early 1970s, and this species then began to reinvade those countries from which it had been eradicated. By the 1990s, *Ae. aegypti* had regained the geographic distribution it had before eradication was initiated (Fig. 72-1). Epidemic dengue invariably followed after reinfestation of a country by *Ae. aegypti*. By the 1980s, the American region was experiencing major epidemics of dengue in countries that had been free of the disease for 35 to 130 years.<sup>34,41,42</sup> With increased epidemic activity came the development of hyperendemicity and the emergence of epidemic DHF, much as had occurred in Southeast Asia 25 years earlier.<sup>41,43</sup> From 1981 to 2005, 28 American countries reported laboratory-confirmed DHF<sup>34,35,42,44</sup> (Fig. 72-2).

While Africa has not yet had a major epidemic of DHF, sporadic cases of severe disease have occurred as epidemic dengue fever has increased markedly in the past 15 years. Before the 1980s, little was known of the distribution of dengue viruses in Africa. Since then, however, major epidemics caused by all four serotypes have occurred in both East and West Africa.<sup>34,35</sup> Recent epidemics include Djibouti in 1991 and Jeddah, Saudi Arabia, in 1994, both of which were the first outbreaks in those countries in over 50 years.<sup>34,35,45</sup>

In 2005, dengue viruses and *Ae. aegypti* mosquitoes have a worldwide distribution in the tropics with over 2.5 billion

**FIGURE 72-1** *Aedes aegypti*: Distribution in the Americas, 1930s, 1970, and 2005.

people living in dengue-endemic areas.<sup>8,34,35,44</sup> Currently, dengue fever causes more illness and death than any other arboviral disease of humans. Each year, an estimated 50 to 100 million dengue infections and several hundred thousand cases of DHF occur, depending on epidemic activity.<sup>35,44,46,47</sup> DHF is a leading cause of hospitalization and death among children in many Southeast Asian countries.<sup>36</sup>

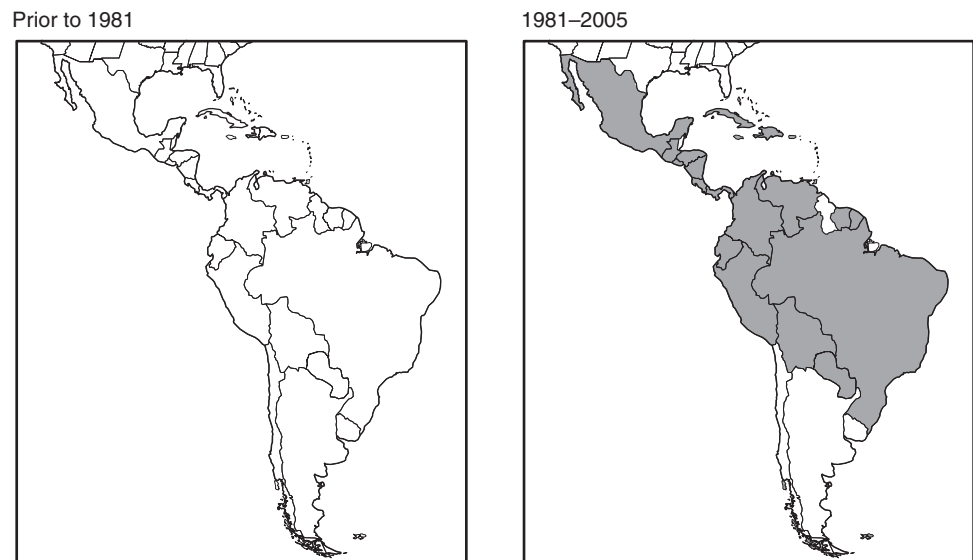

### Factors Responsible for Increased Incidence

The emergence of epidemic dengue and DHF as a global public health problem in the past 25 years is closely associated with demographic and societal changes that have occurred over the past 50 years.<sup>34,35</sup> A major factor has been the unprecedented population growth and, with that, unplanned and uncontrolled urbanization, especially in tropical developing countries. The substandard housing and the deterioration in water, sewer, and waste management systems associated with

unplanned urbanization have created ideal conditions for increased transmission of mosquito-borne diseases in tropical urban centers.

A second major factor has been the lack of effective mosquito control in dengue-endemic areas.<sup>34,35</sup> Emphasis during the past 30 years has been on space spraying with insecticides to kill adult mosquitoes; this has not been effective<sup>48,49</sup> and, in fact, has been detrimental to prevention and control efforts by giving citizens of the community and government officials a false sense of security.<sup>48</sup> Additionally, the geographic distribution and population densities of *Ae. aegypti* have increased, especially in urban areas of the tropics, because of increased numbers of mosquito larval habitats in the domestic environment. The latter include nonbiodegradable plastics and used automobile tires, both of which have increased dramatically during this same period of time.

Another major factor in the global emergence of dengue and DHF is increased air travel by humans, which provides

**FIGURE 72-2** Dengue hemorrhagic fever in the Americas prior to 1981 and from 1981 to present.

The global distribution of dengue/dengue hemorrhagic fever and the principal mosquito vector, *Aedes aegypti*, 2005.

- Areas infested with *Aedes aegypti*
- Areas with *Aedes aegypti* and dengue epidemic activity

the ideal mechanism for the transport of dengue and other urban pathogens between population centers of the world.<sup>34,35</sup> For instance, in 1994, an estimated 40 million persons departed the United States by air, 51% of whom traveled for business or holiday to tropical dengue-endemic countries.<sup>50</sup> Many travelers become infected while visiting tropical areas, but become ill after returning home, resulting in a constant movement of dengue viruses in infected humans to all areas of the world and ensuring repeated introductions of new dengue virus strains and serotypes into areas where the mosquito vectors occur. The result is increased epidemic activity, the development of hyperendemicity, and the emergence of epidemic DHF.

The United States is not immune to the introduction of dengue viruses. Each year for the past 25 years, imported dengue cases have been documented by the Centers for Disease Control and Prevention (CDC; unpublished data, 2004).<sup>50,51</sup> These cases represent introductions of all four virus serotypes from all tropical regions of the world. Most dengue introductions into the United States come from the American and Asian tropics and reflect the increased number of Americans traveling to those areas. Overall, from 1976 to 2003, 3697 suspected cases of imported dengue were reported to the CDC (CDC, unpublished data, 2004).<sup>50,51</sup> Although adequate blood samples were received from only a portion of these patients, 875 (24%) have been confirmed as dengue.

These cases represent only the tip of the iceberg because most physicians in the United States have a low index of suspicion for dengue, which is often not included in the differential diagnosis, even if the patient recently traveled to a tropical country. As a result, many imported dengue cases are never reported. It is important to increase awareness of dengue and DHF among physicians in temperate areas, however, because

the disease can be life-threatening. For example, two cases of the severe form of DHF, dengue shock syndrome (DSS), were described in Swedish tourists returning from holiday in Asia.<sup>52</sup> In the United States, severe disease does occur among imported cases of dengue.<sup>53</sup> It is important, therefore, that physicians in the United States consider dengue in the differential diagnosis of viral syndrome in all patients with a travel history to any tropical area.

The potential for epidemic dengue transmission in the United States still exists. On seven occasions in the past 25 years (in 1980 after an absence of 35 years, and in 1986, 1995, 1997, 1998, 1999, and 2001), autochthonous transmission occurred secondary to importation of the virus in humans (Table 72-1). Of interest was the 2001 Hawaii outbreak, which was the first dengue transmission in that state in 56 years<sup>54</sup> caused by DENV-1 virus introduced from Tahiti where a major

epidemic of DHF was occurring.<sup>55</sup> Transmission in Hawaii was sporadic and illness mild; 122 cases were confirmed.<sup>54</sup> Although the outbreaks in the United States have been small, they underscore the potential for dengue transmission in areas where two competent mosquito vectors occur.<sup>34</sup> *Ae. aegypti*, the most important and efficient epidemic vector of dengue viruses, has been in the United States for over 200 years and has been responsible for transmitting major epidemics in the past.<sup>56</sup> Currently, this species is found only in the Gulf Coast states from Texas to Florida, although several foci have recently been reported in Arizona. *Ae. albopictus*, another, but less efficient epidemic vector of dengue viruses, was introduced to the continental United States in the early 1980s and has since become widespread in the eastern half of the country. Although the CDC has ceased surveillance, at last count it occurred in 1044 counties in 36 of the continental states (C.G. Moore, Colorado State University, personal communication, 2004); this species has also been found in Hawaii for over 90 years. Both *Ae. aegypti* and *Ae. albopictus* can transmit dengue viruses to humans, and their presence in the United States increases the risk of autochthonous dengue transmission secondary to imported cases.<sup>32,50</sup>

## DISEASE

Dengue virus infection in humans causes a spectrum of illness, ranging from unapparent or mild febrile illness to severe and fatal hemorrhagic disease. Infection with all four serotypes causes a similar clinical presentation that may vary in frequency and severity. The incubation period varies from 3 to 14 days (average, 4 to 7 days). In dengue-endemic areas, dengue infections are often clinically nonspecific, especially in children, with symptoms of a viral syndrome that has a variety of local names. Important risk factors influencing the proportion of patients who have severe disease during epidemic transmission include the strain and serotype of the infecting virus, the immune status of the individual, the age of the patient, and the genetic background of the human host.<sup>32,36–40,57–59</sup>

### Dengue Fever

Classic dengue fever is primarily a disease of older children and adults. It is characterized by sudden onset of fever and a variety of nonspecific signs and symptoms, including frontal headache, retro-orbital pain, body aches, nausea and vomiting, joint pains, weakness, and rash.<sup>17,21,60,61</sup> Patients may be anorectic, have altered taste sensation, and mild sore throat. Constipation is occasionally reported; diarrhea and respiratory symptoms are infrequently reported and may be due to concurrent infections.

The initial temperature may rise to 102°F to 105°F and last for 2 to 7 days. The fever may drop after a few days only to rebound 12 to 24 hours later (saddleback). Relative bradycardia may be noted despite the fever. The conjunctivae may be injected and the pharynx inflamed. Lymphadenopathy is common. Rash is variable, but occurs in up to 50% of patients as either early or late eruptions. Facial flushing or erythematous mottling may occur coincident with or slightly before onset of fever and disappear 1 to 2 days after onset of symptoms. A second rash, varying in form from scarlatiniform to maculopapular, may appear between days 2 and 6 of illness.

**FIGURE 72-3** Rash associated with dengue infection: Islands of normal skin are surrounded by a confluent rash.

The rash usually begins on the trunk and spreads to the face and extremities. In some cases, an intense erythematous pattern with islands of normal skin may be observed (Fig. 72-3). The average duration of the second rash is 2 to 3 days. Toward the end of the febrile phase of illness or after the temperature reverts to normal, petechiae may appear; these may be scattered or confluent. Intense pruritus may occur followed by desquamation on the palms of the hands and soles of the feet.

Hemorrhagic manifestations in dengue fever patients are not uncommon and may range from mild to severe. Skin hemorrhages are the most common, including petechiae and purpura, as well as gum bleeding, epistaxis, menorrhagia, and gastrointestinal hemorrhage. Hematuria occurs infrequently, and jaundice is rare.

Clinical laboratory findings associated with dengue fever include neutropenia followed by lymphocytosis, often marked by atypical lymphocytes. Liver enzymes in the serum may be elevated; this is usually a mild elevation but, in some patients, alanine transaminase and aspartate transaminase levels may reach 500 to 1000 units/L. In one epidemic of DEN-4, 54% of confirmed patients with data had elevated liver enzymes.<sup>62</sup> Thrombocytopenia is also common in dengue fever; in the preceding epidemic, 34% of confirmed dengue fever patients who were tested had platelet counts of less than 100,000/ $\mu$ L.<sup>62</sup>

Dengue fever is generally self-limited and rarely fatal. The acute phase of illness lasts for 3 to 7 days, but the convalescent phase may be prolonged for weeks and may be associated with weakness and depression. No permanent sequelae are known to be associated with this infection.

### Dengue Hemorrhagic Fever

DHF is primarily a disease of children under the age of 15 years, although it may also occur in adults.<sup>36</sup> It is characterized by sudden onset of fever, usually of 2 to 7 days' duration, and a variety of nonspecific signs and symptoms. During the acute phase of illness, it is difficult to distinguish DHF from dengue fever and other illnesses found in tropical

areas (Table 72-2). The differential diagnosis during the acute phase of illness should include measles, rubella, influenza, typhoid, leptospirosis, malaria, viral hemorrhagic fevers, and any other disease that may present in the acute phase as a nonspecific viral syndrome. Children frequently have concurrent infections with other viruses and bacteria causing upper respiratory symptoms. There is no pathognomonic sign or symptom for DHF (see Table 72-2).

The critical stage in DHF occurs most frequently from about 24 hours before to 24 hours after the temperature falls to normal or below.<sup>36</sup> During this time, hemorrhagic manifestations and, more importantly, signs of circulatory failure usually occur. Blood tests will usually show that the patient has thrombocytopenia (platelet count of  $<100,000/\mu\text{L}$ ) and evidence of a vascular leak syndrome.

Common hemorrhagic manifestations include skin hemorrhages such as petechiae, purpuric lesions, and ecchymoses. Epistaxis, bleeding gums, gastrointestinal hemorrhage, and hematuria occur less frequently. The tourniquet test may be diagnostically helpful. This is done by inflating the blood pressure cuff to the midpoint between the systolic and diastolic pressures for 5 minutes and then releasing the pressure.<sup>36</sup> In persons with increased capillary fragility, a “shower” of petechiae will appear below the cuff. The test is positive if 20 or more petechiae per square inch are observed. Some uninfected persons may have a positive tourniquet test, however, so it does not mean that a person has DHF when the test is positive. Rather, positive results indicate that the patient has increased capillary fragility and that the physician should do further clinical laboratory tests.

Scattered petechiae are the most common hemorrhagic manifestation observed; they appear most often on the extremities, but also on the trunk, other parts of the body, and on the face in severe cases of DSS. Purpuric lesions may appear on various parts of the body but are most common at the site of venipuncture.

In some patients, large ecchymotic lesions develop on the trunk and extremities, and other patients bleed actively at the site of venipuncture, some profusely. More severely ill patients have gastrointestinal hemorrhage, which is manifested by hematemesis or melena or both. Classic hematemesis and melena usually occur after prolonged shock, but patients may develop massive, frank upper gastrointestinal hemorrhage as well, often before the onset of shock. Without early diagnosis and proper management, some patients experience shock from blood loss, which may be mild or severe.<sup>63–65</sup> More commonly, shock is caused by plasma leakage; it may be mild and transient or progress to profound shock with undetectable pulse and blood pressure.<sup>36</sup> Children with profound shock are often somnolent, exhibit petechiae on the face, and have perioral cyanosis.

It is convenient for both clinicians and epidemiologists to classify DHF into four grades of illness based on severity<sup>36</sup> (Box 72-1). Grade I DHF is mild; the only hemorrhagic manifestations are scattered petechiae or a positive tourniquet test. Grade II DHF is more severe, with one or more overt hemorrhagic manifestations such as those mentioned previously. Grades III and IV represent more severe forms of disease (DSS). Grade III illness is characterized by mild shock with signs of circulatory failure; the patient may be lethargic or restless and have cold extremities, clammy skin, a rapid but weak pulse, narrowing of pulse pressure to 20 mm Hg or less, or hypotension. Grade IV, the most severe form of DHF or DSS, is characterized by profound shock with undetectable pulse and blood pressure.

In severe cases of DHF and DSS, fever and nonspecific constitutional signs and symptoms of a few days' duration are followed by the sudden deterioration of the patient's condition. During or shortly before or after the fall in temperature, the patient's skin may become cool, blotchy, and congested; circumoral cyanosis is frequently observed, and the pulse becomes rapid and weak. Although some patients appear lethargic at first, they become restless and then rapidly pass into a critical stage of shock. They frequently experience acute abdominal pain shortly before the onset of shock.<sup>36,63,65</sup>

In mild cases of DHF, all signs and symptoms abate shortly after the fever subsides. Lysis of fever, however, may be accompanied by profuse sweating and mild changes in pulse rate and blood pressure, together with coolness of extremities and skin congestion. These changes reflect mild and transient

#### Box 72-1 World Health Organization Classification of Dengue Hemorrhagic Fever

- Grade I: Fever accompanied by nonspecific constitutional symptoms, with a positive tourniquet test or scattered petechiae as the only hemorrhagic manifestation
- Grade II: The same as grade I, but with spontaneous hemorrhagic manifestations
- Grade III: Circulatory failure manifested by rapid, weak pulse; narrowing of pulse pressure ( $\leq 20$  mm Hg); or hypotension
- Grade IV: Profound shock with undetectable pulse and blood pressure

From World Health Organization: Dengue Hemorrhagic Fever: Diagnosis, Treatment and Control, Geneva, 2nd ed. World Health Organization, 1997.

circulatory disturbances as a result of plasma leakage. Patients usually recover spontaneously or after fluid and electrolyte therapy.<sup>36</sup> Patients in shock are in danger of dying without appropriate management. The duration of shock is usually short; the patient may die within 8 to 24 hours or recover rapidly following antishock therapy. Convalescence for patients with DHF, with or without shock, is usually short and uneventful. Even in patients with undetectable pulse and blood pressure, once the shock is overcome surviving patients usually recover within 2 to 3 days.

As with dengue fever, leukopenia is common; thrombocytopenia and hemoconcentration are constant findings in DHF and DSS. A platelet count of less than 100,000/ $\mu$ L is usually found between the third and eighth day of illness. Hemoconcentration, indicating plasma leakage, is almost always present in classic DHF, but is more severe in patients with shock. Hepatomegaly is a common, but not a constant, finding.<sup>63-65</sup> In some countries, most patients with confirmed DHF or DSS have been found to have an enlarged liver. In other countries, however, hepatomegaly varies from one epidemic to another, suggesting that the strain or serotype of virus may influence liver involvement.<sup>64</sup> Elevated liver enzymes are common.

The primary pathophysiologic abnormality seen in DHF and DSS is an acute increase in vascular permeability that leads to leakage of plasma into the extravascular compartment, resulting in hemoconcentration and decreased blood pressure.<sup>36</sup> Plasma volume studies have shown a reduction of more than 20% in severe cases. Supporting evidence of plasma leakage includes serous effusion found post mortem, pleural effusion on radiograph, hemoconcentration, and hypoproteinemia. There are no apparent destructive vascular lesions, suggesting that the transient functional vascular changes are due to a short-acting chemical mediator.<sup>36</sup>

Hemostatic changes in DHF and DSS involve three factors: vascular changes, thrombocytopenia, and coagulation disorders.<sup>36</sup> Almost all DHF patients have increased vascular fragility and thrombocytopenia, and many have abnormal coagulograms, suggesting disseminated intravascular coagulation, which is also evidenced by concomitant thrombocytopenia, prolonged partial thromboplastin time, decreased fibrinogen level, and increased fibrin(ogen) degradation products. Gastrointestinal hemorrhage is found at autopsy in the majority of patients who die.

### Atypical Dengue Infection

Some cases of severe hemorrhagic disease do not fit the preceding classification and may have a different pathogenesis.<sup>32,65</sup> These patients generally present with similar signs and symptoms during the acute phase of illness, but develop frank upper gastrointestinal bleeding without evidence of plasma leakage (hemoconcentration) or circulatory failure as seen in patients with classic DHF or DSS. Generally, the upper gastrointestinal bleeding occurs 3 to 5 days after onset of illness and is often the reason the patient is brought to the hospital. All such patients have significant thrombocytopenia. In many cases, bleeding may be severe enough to cause shock from blood loss rather than plasma leakage. In one study in Indonesia, 30% of patients with virologically confirmed fatal DHF had this type of severe upper gastrointestinal hemorrhaging.<sup>65</sup> Blood transfusions are always indicated for these

patients, whose disease is generally more difficult to manage than classic DSS.<sup>65</sup>

Finally, some patients with dengue infection may present with neurologic disorders such as convulsions, spastic paresis, and change in consciousness, with or without hemorrhagic manifestations.<sup>65,66</sup> These patients, who may be admitted to the neurologic ward with a diagnosis of viral encephalitis, may subsequently develop hemorrhagic manifestations and shock. Cerebrospinal fluid findings are normal, and most evidence suggests that the virus does not cross the blood-brain barrier, although recent studies suggest that this may occur in some patients.<sup>67-69</sup> Further studies are necessary to identify what factors contribute to these unusual manifestations.

### PATHOGENESIS AND IMMUNITY

The pathogenesis of DHF and DSS is still controversial. Two theories, which are not mutually exclusive, are frequently cited to explain the pathogenic changes that occur in DHF and DSS. The theory most commonly accepted is known as the secondary infection, or immune enhancement, hypothesis.<sup>36,37,57</sup> This hypothesis implies that patients experiencing a second infection with a heterologous dengue virus serotype have a significantly higher risk of developing DHF or DSS. Pre-existing heterologous dengue antibody recognizes the infecting virus and forms an antigen-antibody complex which is then phagocytosed by macrophages. Because the antibody is heterologous, however, the virus is not neutralized and is free to replicate once inside the macrophage. Thus, it is hypothesized that prior infection enhances the infection of cells of the mononuclear cell lineage by a virus that is not inactivated by neutralizing antibody. Infection of these cells initiates an immunologic cascade of events that produces cytotoxins and other vasoactive mediators, ultimately leading to increased vascular permeability, leakage, hypovolemia, shock/and death, if not corrected.<sup>70</sup>

The other hypothesis assumes that dengue viruses, like all animal viruses, vary and change genetically as they move through human or mosquito populations, and that there are some virus strains that have greater pathologic potential.<sup>58,59,71</sup> Data suggest that genetic changes in the virus genome occur randomly as the viruses are passed in nature. Some of these genetic changes are advantageous and are propagated through natural selection, resulting in viruses that have increased virus replication and higher viral load, greater epidemic potential, and increased virulence. There is epidemiologic and laboratory evidence to support both of these hypotheses, a discussion of which is beyond the scope of this chapter; most likely, both are valid. While immune enhancement may occur and may be an important factor in the pathophysiologic changes that occur in DHF and DSS, it appears that only certain strains of virus may be involved in producing severe disease by immune enhancement.

### DIAGNOSIS

A definitive diagnosis of dengue infection can be made only in the laboratory and depends on isolating the virus, detecting dengue virus specific RNA sequences by nucleotide amplification test, or detecting specific antibodies in the patient's serum.<sup>72-74</sup> An acute-phase blood sample should always be taken as soon as possible after onset of illness, and a

convalescent-phase sample should be taken 2 to 3 weeks later. Because it is frequently difficult to obtain convalescent-phase samples, however, a second blood sample should always be taken from hospitalized patients on the day of discharge from hospital.

Virus can often be isolated from acute-phase blood samples taken in the first 5 days of illness.<sup>72–74</sup> Viral RNA can often be detected by polymerase chain reaction (PCR) in serum or tissues<sup>74,75</sup> or antigen by immunohistochemistry in tissues.<sup>76</sup> Two serologic tests are used to detect antibodies. The IgM capture enzyme-linked immunosorbent assay (ELISA) detects IgM antibody, which usually appears by day five after onset and persists for 2 to 3 months.<sup>72–74,77–79</sup> The hemagglutination-inhibition test and an IgG ELISA detect IgG antibody, which appears simultaneously or shortly after IgM but persists for life. For this reason, diagnosis using IgG requires paired acute- and convalescent-phase blood samples to demonstrate a fourfold or greater rise in specific antibody, which should be confirmed by neutralization test.<sup>72,73</sup>

## TREATMENT

There is no specific chemotherapy for DHF/DSS. However, early and effective fluid replacement of lost plasma with electrolyte solutions, plasma, or plasma expanders usually results in a favorable outcome.<sup>36</sup> With adequate fluid administration, DSS is reversible. Rapid replacement of fluid will usually prevent disseminated intravascular coagulation. Prognosis depends on early recognition of shock, based on careful monitoring.

In dengue-endemic areas, it is often not possible or necessary to hospitalize all patients with suspected DHF or DSS, since shock may develop in only about one-third of the patients.<sup>36</sup> A decrease in the platelet count, which usually precedes the rise in hematocrit, is of great diagnostic and prognostic value. In order to be able to recognize the early signs of shock and thus take preventive action, parents or family members should be advised to bring the patient back for repeat platelet and hematocrit determinations every 24 hours. They should also be instructed to keep a careful watch for any signs of clinical deterioration or warning signs of shock, such as restlessness, lethargy, acute abdominal pain, cold extremities, skin congestion, or oliguria, usually on or after the third day of illness. Patients with mild DHF can usually be rehydrated orally. An antipyretic drug may be all that is needed. Salicylates should be avoided.

Patients should be hospitalized and treated immediately if they have any signs or symptoms of shock, such as restlessness; lethargy; cold extremities; circumoral cyanosis; rapid, weak pulse; narrowing of pulse pressure to 20 mm Hg or less; hypotension; a sudden rise in hematocrit; or continuously elevated hematocrit despite the administration of intravenous fluids.<sup>36</sup> Frequent recording of vital signs and hematocrit determinations and monitoring of urine output are important in evaluating the results of treatment. Blood transfusions are contraindicated in patients with severe plasma leakage in the absence of hemorrhage and, if given, may cause pulmonary edema; however, they may be indicated for patients with significant clinical bleeding. It may be difficult to recognize internal bleeding in the presence of hemoconcentration. A drop in hematocrit of 10% with no clinical improvement, despite adequate fluid administration, suggests significant internal hemorrhage.<sup>36</sup> Transfusion of fresh whole blood is

preferable; fresh frozen plasma or concentrated platelets may be indicated in some cases when consumptive coagulopathy causes massive bleeding.

Some controversy surrounds the use of steroids, but the consensus is that they have no beneficial effect in management of severe DHF or DSS. Although some physicians still use steroids in the treatment of shock cases, two double-blind studies, in Thailand and Indonesia, have shown no increase in survival rates of patients with grade IV DSS who were administered steroids.<sup>36</sup>

## PREVENTION

Prevention and control of dengue fever/DHF currently depends on controlling the mosquito vector, *Ae. aegypti*, in and around the home where most transmission occurs. Space sprays with insecticides to kill adult mosquitoes are usually ineffective, unless they are sprayed indoors where the mosquitoes are resting. The most effective way to control the mosquitoes that transmit dengue is larval control, including eliminating, cleaning, or chemically treating water-holding containers that serve as the larval habitats for *Ae. aegypti* in the domestic environment.<sup>47–49,80</sup> At present, there is no vaccine for dengue viruses, although several candidates are at various stages of development.<sup>81–83</sup> To be effective, a dengue vaccine must protect against all four virus serotypes, i.e., be a tetravalent formulation. For use in dengue endemic countries, a dengue vaccine must be safe for use in children 9 to 12 months of age, must be economical, and should provide long lasting protective immunity (ideally more than 10 years).

Several approaches are being used to develop dengue vaccines. A live attenuated vaccine (LAV) is thought to provide the most complete and lasting immunity. At present, there are three LAV candidates under development.<sup>81–86</sup> Several groups have also constructed chimeric viruses using various infectious clones as backbones.<sup>87–89</sup> All of these chimeric candidate vaccines look very promising in primate studies. The 17-D yellow fever chimeras have recently undergone a Phase I trial in humans, but results are not yet available.

In summary, there are at least six tetravalent candidate dengue vaccines that are in or near clinical trials in humans. The Pediatric Dengue Vaccine Initiative, funded by the Bill and Melinda Gates Foundation, was founded to facilitate bringing one or more of these promising candidate vaccines to fruition.<sup>90</sup>

There is no completely effective method of preventing dengue infection in travelers to tropical areas. The risk of infection can be significantly reduced, however, by understanding the basic behavior and habits of the mosquito vector and by taking a few simple precautions, such as using aerosol bomb insecticides to kill adult mosquitoes indoors, using a repellent containing diethyltoluamide (DEET) on exposed skin, and wearing protective clothing treated with a similar repellent. The risk of exposure may be lower in modern, air-conditioned hotels with well-kept grounds, and in rural areas.

# Japanese Encephalitis and West Nile and Other Flavivirus Infections

DOUGLAS M. WATTS  
BRUNO P. GRANWEHR  
ROBERT E. SHOPE  
TOM SOLOMON  
ROBERT B. TESH

## INTRODUCTION

Four mosquito-transmitted flaviviral diseases are of significant public health importance in tropical and subtropical regions of the world: dengue, yellow fever, Japanese encephalitis, and West Nile virus infection. Other chapters in this book address dengue and yellow fever; this chapter focuses on disease caused by Japanese encephalitis (JE) and West Nile (WN) viruses. Among the other tropical flaviviruses that cause human disease (Tables 73-1 and 73-2), Murray Valley encephalitis (MVE), Rocio, Kyasanur Forest disease (KFD), and Zika viruses will be described very briefly. Kunjin is not included because it is a subtype of WN virus and is not

**Table 73-1** Tropical Flaviviruses Causing Encephalitis\*

Virus	Distribution	Frequency of Disease
Japanese encephalitis	Asia, Pacific Islands	>10,000/yr; most epidemics in temperate region
West Nile	Africa, Asia, Europe, U.S.	Uncommon in tropics
Ilheus	South America	Uncommon
Kunjin	Australia	Uncommon
Murray Valley encephalitis	Australia	0–50/yr; uncommon in tropics
Rocio	São Paulo, Brazil	971 cases 1975–1976; last diagnosed in 1980
St. Louis encephalitis	Americas	Epidemics in the United States; uncommon in tropics

\*The viruses causing these diseases have a natural cycle involving *Culex* or *Aedes* mosquitoes and birds.

**Table 73-2** Tropical Flaviviruses Associated Primarily with Fever\*

Virus	Distribution	Associated Clinical Syndrome
Banzi	Africa	—
Bussuquara	South and Central America	Arthralgia
Edge Hill	Australia	Arthritis
Kokobera	Australia	Rash
Koutango	Africa	Rash
Rio Bravo	North America, Trinidad	—
Sepik	Papua New Guinea	—
Spondweni	Africa	—
Usutu	Africa	Rash
Wesselsbron	Africa, Southeast Asia	—
Zika	Africa, Southeast Asia	Rash

\*These diseases are uncommon; 12 or fewer cases of each are described. Not listed is Kyasanur Forest disease virus, which causes hemorrhagic disease in India.

a frequent cause of human disease.<sup>1</sup> St. Louis encephalitis (SLE) virus has been isolated sporadically from patients in the tropics, but will not be described because epidemics are limited to temperate regions.

## AGENTS

Both JE and WN viruses are members of the Japanese encephalitis serocomplex of the genus *Flavivirus*, family *Flaviviridae*.<sup>2</sup> These viruses measure about 50 nanometers in diameter and are enveloped, icosahedral virions with single-stranded, positive-sense RNA genomes of approximately 11,000 nucleotides. The three main structural proteins are the envelope (E), matrix (M), and the capsid (C) proteins. The E protein in the lipid envelope comprises the major surface protein that is thought to be responsible for virulence by mediating viral entry into cells, tissue tropism, and host range. The M proteins are responsible for the maturation of virions, and the C protein is an essential component of the virion nucleocapsids. Virus replicates in the cytoplasm, and viral assembly and maturation occur in the lumen of the endoplasmic reticulum preceding release from the host cell.

## EPIDEMIOLOGY

### Japanese Encephalitis Virus

JE virus is enzootic in rural agricultural areas throughout much of eastern and southern Asia and the Pacific Islands.<sup>3–5</sup> The principal enzootic transmission cycle involves various species of *Culex* mosquitoes and vertebrates, with *Culex tritaeniorhynchus* being the most important vector of human infections. These mosquitoes breed in rural areas, especially in flooded rice paddies, and are predominantly exophilic and zoophilic, preferring to feed on swine and birds and to a lesser extent on humans. Domestic swine and ardeid birds, such as herons and other waterfowl are the most important virus-amplifying hosts. However, the most important source of human infections is linked to the mosquito–swine transmission cycle. JE virus infection in avians does not normally cause any apparent illness, but abortions occur in infected

pregnant sows. Human and equines are believed to be dead-end hosts because their infection does not produce viremia of sufficient magnitude to infect the mosquito vectors. While several other domestic and feral animals are infected in nature, their roles in the transmission cycle are unknown.

JE virus is a leading cause of viral encephalitis in tropical Asia, where it causes an estimated 35,000 to 50,000 clinical cases and 15,000 deaths annually.<sup>6,7</sup> Human infection and/or disease in temperate zones and the northern region of the tropical zone (northern Thailand, northern Vietnam, China, Korea, Japan, Taiwan, Nepal and northern India) is seasonal, and the incidence varies depending on vaccination practices and climatic conditions. The most common pattern of infection in northern (temperate) regions of Asia is summer epidemics; whereas, in southern (tropical) regions of Asia (southern Thailand, southern Vietnam, Malaysia, Singapore, Indonesia, the Philippines, Sri Lanka, and southern India), an endemic pattern of infection occurs with sporadic cases throughout the year and peak case rates appearing after the beginning of the rainy season.<sup>8</sup> In some countries, such as Japan, Taiwan, Korea, and China, the number of JE cases has been markedly reduced by the implementation of childhood immunizations.<sup>9</sup> However, over the past four decades, the incidence of JE has increased dramatically in central and northern India, Nepal, and the northern region of Southeast Asia. JE virus has also expanded its range into other areas of Southeast Asia and eastward to the Australasian zoogeographic region.<sup>10</sup> The expanding distribution of JE is not fully understood, but may be associated with changes in agricultural practices that provide suitable breeding habitat for mosquitoes or an increase in swine production.

The risk of JE infection is highest among individuals who travel or live in rural areas where rice is grown and swine are raised in close proximity to human dwellings.<sup>3–5,8</sup> In endemic areas, the annual infection rate is about 10% among the susceptible populations, with about 85% of the cases occurring among children under 15 years of age.<sup>11</sup> Most JE virus infections are silent; the ratio of symptomatic to asymptomatic infections varies from about one in 25 to one in 1000.<sup>4</sup> The lower incidence among adults in Asia has been attributed to high rates of immunity. The case-fatality rate among JE patients admitted to the hospital is about 25% to 30%; about half of the survivors experience severe neuropsychiatric sequelae.<sup>3,7</sup> In contrast to the situation in endemic regions, all age groups are affected during epidemics in nonimmune populations.<sup>12</sup> Similarly, when nonimmune individuals (travelers, or military personnel) visit endemic areas they too are at risk.

### West Nile Virus

West Nile virus (WNV) is enzootic in most of Africa, southern Europe, the Middle East, western Asia, Australia, and North America.<sup>13–15</sup> The basic transmission cycle of the virus is similar throughout its range, involving mainly *Culex* mosquitoes as the primary vector and a variety of passerine birds as the major amplifying hosts. Infection of avians is usually benign in most species; however, epizootics with high mortality have been documented among certain species of birds (crows, jays, geese) during epidemics of WN in the United States, Canada, and Israel. While infection of other vertebrates, including humans and equines, is common, they

are considered to be dead-end hosts because the level of viremia is thought to be insufficient to infect mosquito vectors. WNV has been isolated from a wide variety of other mosquito species, at least 40 species in Africa, Europe, and Asia and 37 species in North America. Recovery of WNV from mosquito species other than *Culex*, such as *Aedes* and *Ochlerotatus*, suggests that they might act as bridging vectors to transmit virus to humans and birds.<sup>16,17</sup> Experimental studies suggest that vertical transmission by infected mosquitoes and the overwintering of infected adult mosquitos may be important in the maintenance and transmission cycle of WNV. While the primary source of human infections is the bite of infected mosquitoes, observations during outbreaks in the United States in 2002 indicated that WNV could also be transmitted by other routes,<sup>17</sup> including transplanted organs, transfusion of blood products, transplacental spread, possibly breast milk, and accidental laboratory exposure. Estimates in the United States indicated that the risk of blood transfusion transmission was as high as 21 per 10,000 blood donations during the peak of the 2002 WN epidemic. However, screening of blood donations since 2003 has greatly reduced the risk of infection via blood products.

WNV is the cause of sporadic infections and outbreaks among humans, equines, and certain avian populations.<sup>13,15,18</sup> Until the mid-1990s, WNV was usually associated with sporadic cases and infrequent outbreaks of a febrile illness (fever, arthralgia, and rash), with occasional central nervous system disease. Recently, the epidemiology has changed to a pattern of more frequent and widespread outbreaks, with a marked increase in the incidence of human neurologic disease. Some of the better documented examples of this changing pattern were epidemics in Algeria during 1994, Romania in 1996 and 1997, Tunisia and the Czech Republic in 1997, Congo in 1998, Russia in 1998 and 1999, Israel in 1999 and 2000, and annually in the United States from 1999 through 2003. These epidemics and epizootics affected both urban and rural populations. The most surprising spread of WNV was to the New York City metropolitan area during 1999.<sup>19</sup> Although the mechanism of introduction is unknown, nucleotide sequence data revealed that the New York strain is closely related to a viral strain isolated from a goose in Israel the year before.<sup>20</sup> Since 1999, WNV has spread throughout the continental United States, southern Canada, Mexico, and the Caribbean.<sup>17,21–23</sup> The pattern of spread has been rapid and extensive; 62 human cases were documented in the United States during 1999 and 66 in 2001. However, more than 4000 cases were reported in 2002, primarily in the Ohio and Mississippi River basins. Also during the same year, the first cases were diagnosed in at least 5 provinces of Canada, including 400 cases in Ontario and Quebec. In 2003, a total of 9100 WN cases and 222 deaths were reported from 45 states and the District of Colombia in the United States.

It is assumed that the virus will continue its move southward from Central America into South America. However, the risk of severe disease among persons living in tropical America may be less because of the high prevalence of heterologous flavivirus immunity. Experimental studies in animals suggest that prior infection with dengue, St. Louis encephalitis, or the yellow fever 17-D vaccine virus provides protection against severe disease and death upon challenge with WNV.<sup>24,25</sup>

About 20% of WNV-infected persons during the epidemic in New York developed symptoms, and less than 1% of infections resulted in severe life-threatening neurologic illness, with the most commonly reported severe syndromes being encephalitis, meningitis, and meningoencephalitis.<sup>26</sup> The ratio of clinical to subclinical infection in Romania during the 1996 outbreak was lower, ranging from 1:140 to 1:320.<sup>27</sup> While the age-specific rates of WN infection are similar, the risk of illness among those over 50 years old is 10 times greater than among those 0 to 19 years of age.<sup>19,21</sup> Severe disease can occur at any age, but the elderly, young adolescent, and immunocompromised individuals are at greater risk for the severe neurologic syndromes.<sup>19,27,28</sup> The impact of severe disease among the elderly was reported during an outbreak in Israel during 2000.<sup>28</sup> Among 50 patients admitted to one hospital, 32 (64%) were age 65 or older and 22% died, all of them aged 78 years or older. During the 1996 outbreak in Romania, among 352 cases of acute central nervous system infections, 40% presented with meningitis, 44% with meningoencephalitis, and 16% had encephalitis.<sup>27</sup> The overall mortality rate was 5%, and all of the fatal cases were greater than 50 years of age. In the 1999 outbreak in New York, the median age of 62 hospitalized cases was 71 years, ranging from 5 to 90 years, with 88% being at least 50 years old. Sixty-three percent presented with encephalitis, 29% with meningitis, and 8% had a febrile illness. In these outbreaks, the average fatality rate for severe cases of WN was between 4% and 18%, with rates as high as 21% and 29% reported among the elderly in the United States and Israel, respectively.<sup>22,29</sup>

WN disease in pediatric populations is less frequent and not as severe as in adults. However, the disease spectrum ranges from a nonspecific febrile illness to severe cases involving the central nervous system. In the United States, 5% (11/225) of cases in 2002 involved individuals 18 years old and younger. Of these patients, seven (64%) required hospitalization, five for meningitis and two for encephalitis, and the other four were diagnosed with WN fever at an outpatient clinic.<sup>21,30</sup>

## DISEASES

### Japanese Encephalitis Virus

JE virus infection can begin as a mild febrile illness or aseptic meningitis, but by far the most common presentation to hospital in humans is due to acute meningomyeloencephalitis. After an incubation period of 1 to 2 weeks, patients typically present with a history of 1 to 3 days of fever, headache, stupor, and, especially in children, generalized motor seizures. Physical findings at this time may be limited to a depressed state of consciousness, but evidence of local motor impairment of limbs or cranial nerve palsy is not infrequent. Some patients have a rapid recovery, but most will develop a variety of neurologic manifestations. The case-fatality rate can be as high as 30%. In some instances, abnormal behavior is the only presenting symptom, without fever, weakness, diarrhea, vomiting, confusion, and rigors. Upper motor neuron weakness is noted in 30% to 50% of patients<sup>31</sup> in contrast with poliomyelitis-like flaccid paralysis occurring in up to 15% of patients.<sup>32</sup> This poliomyelitis-like syndrome may present with an altered level of consciousness progressing to encephalitis and respiratory paralysis in 20% to 60%, with poor prognosis

for recovery.<sup>7,31</sup> A parkinsonian syndrome is seen in up to 25% of patients, typified by cogwheel rigidity, mask-like facies, and bradykinesia. Other movement disorders consist of myoclonic jerks and haunting orofacial dyskinesias (grimacing, chewing, and lip smacking) noted in up to a third of patients during recovery and also seen with WNV infection.<sup>33</sup>

Seizures occur in 85% of children and 10% of adults.<sup>31</sup> Uncontrolled seizures and elevated intracranial pressure demonstrated by opening pressure of greater than 25 mm Hg during lumbar puncture are predictive of poor outcome.<sup>34</sup> In fact, the mortality rate in patients with such findings, as well as prolonged illness, was 62% compared with 14% overall in one study including adults and children.<sup>34</sup> The long-term outcome of JE is grim, with survivors sharing a variety of deficits including 20% with severe cognitive and language impairment, 20% with subsequent seizures, 30% with flexion or extension contractures, and learning/behavioral disorders.<sup>7</sup> Other unfortunate complications, such as decubitus ulcers and pneumonia, are due to the disability caused by the virus rather than direct viral damage.<sup>35</sup>

Bilateral lesions in the thalamus, basal ganglia, and brainstem on brain MRI and CT scan correlate with the clinical manifestations.<sup>36,37</sup> Hyponatremia is presumably caused by inappropriate release of antidiuretic hormone.

### Pathology

Virus is found in lungs, liver, kidneys, and myocardium as well as various regions of gray matter such as the thalamus, basal ganglia, and midbrain. A distinguishing feature of JE is predominant gray matter infection that spares white matter, unlike WN.<sup>7,36,38</sup> Prolonged viremia may occasionally occur for weeks to months,<sup>39</sup> a phenomenon recently noted in WNV infection as well, and postulated to lead to rare chronic progressive CNS infection.

### West Nile Virus

After exposure to WNV, the incubation period usually ranges from 2 to 6 days, but may extend to 14 days, and as long as 21 days, for patients following organ transplantation.<sup>22,30,40</sup> WN fever is typically a mild illness, lasting 3 to 6 days. Infected individuals develop a sudden onset of high fever with chills, rash, malaise, headache, backache, arthralgia, myalgia, and eye pain. Other nonspecific manifestations may include nausea, vomiting, anorexia, diarrhea, rhinorrhea, sore throat, and cough. In some patients, there is generalized lymphadenopathy, and an erythematous macular, papular, or morbilliform eruption involves the entire body. A biphasic fever may occur that is similar to dengue fever.

Meningitis, encephalitis, and/or acute flaccid paralysis develop in less than 1% of WNV-infected individuals.<sup>22,26,27</sup> Patients with neurologic disease typically have a febrile prodrome of 1 to 7 days, which may be biphasic before they develop neurologic symptoms. While the prodrome phase is usually nonspecific, 15% to 20% of the patients may have features characteristic of WN fever, including ocular pain, facial congestion, or a rash, and less than 5% have lymphadenopathy. Typically, most patients present with a fever, stiff neck, headache, muscle weakness, gastrointestinal symptoms, disorientation, tremors, convulsions, and paralysis.

While about 30% of patients have been reported to have convulsions, the rates were much lower during outbreaks in Romania and New York. Patients with encephalitis have altered mental status or cortical signs. Other neurologic manifestations associated with WNV infection include cranial neuropathies, optic neuritis, ataxia, and seizures. Stiffness, rigidity, spasms, and tremors have been associated with basal ganglia damage during WN encephalitis. Ocular manifestations, myocarditis, pancreatitis, and fulminant hepatitis may also occur.

## Pathology

Fatal cases reveal variable amounts of neuronal necrosis in the gray matter, microglial nodules, polymorphonuclear leukocytes, perivascular and leptomeningeal chronic inflammation, and neuronophagia.<sup>38</sup> Viral antigens are present in neurons, neuronal processes, and areas of necrosis in the brain and spinal cord, but not in the lung, liver, spleen, and kidney.

## PATHOGENESIS

The pathogenesis of JE and WNV infection is similar with interplay between direct viral damage and the pathologic effects of the host immune response.<sup>41</sup> Infection is believed to begin with the replication of virus in the skin and regional lymph nodes to produce a primary viremia, which leads to infection of the reticuloendothelial system.<sup>29,42</sup> A secondary viremia follows, that may result in a systemic infection involving other organs and the central nervous system. Observations on patients who died after inoculation with WNV during cancer treatment studies suggested that the virus replicated in the spleen, lymph nodes, liver, and lungs, similar to studies in laboratory animals. WN viremia is transient, lasting only for a few days, and then ceases with the onset of symptoms and concurrent development of IgM and IgG antibodies. Immunocompromised individuals may have prolonged viremia and delayed development of symptoms and IgM antibody. The increased incidence and higher mortality rate of WN encephalitis in the elderly and immunocompromised individuals suggest that host factors are important determinants of the outcome of infection, such as immune senescence or changes in the blood-brain barrier.<sup>29</sup> The associations between neurocysticercosis in JE<sup>41</sup> and hypertension in WNV infection suggest a potential role for factors that make the blood-brain barrier vulnerable to invasion.<sup>38</sup> The capability to mount an early immune response plays a critical role in containing viral replication and dissemination in the CNS of mice.<sup>43</sup> The use of viral mutations to study viral virulence indicates that the major determinants for neuroinvasiveness are on the WN virion E protein, similar to other flaviviruses.

## DIAGNOSIS

The etiologic diagnosis of a flaviviral infection cannot be determined clinically. A high index of suspicion, however, can be gleaned from the geographic area of exposure, history of arthropod abundance, and season of the year. In addition, specific clinical features, such as flaccid paralysis, unusual movement disorders, or subtle motor seizures may provide an

additional clue. Leukopenia, when present, may be an indication of a viral illness. Encephalitis cases usually have pleocytosis between 5/ $\mu$ L and greater than 1000/ $\mu$ L, and initially this may be characterized by polymorphonuclear cells, but subsequently lymphocytes predominate; there is usually a normal cerebrospinal fluid to plasma glucose ratio, and an increased concentration of protein in the cerebrospinal fluid.<sup>44</sup>

The laboratory diagnosis of a febrile or neurologic case of JE or WN infection can be made by a variety of tests. Blood samples should be obtained as early as possible from suspected cases and tested for virus in cell culture or for genomic sequences by the PCR assay. In most cases of encephalitis, the period of viremia has ceased by the time the patient seeks medical care, and virus isolation from the blood will not be possible.<sup>44</sup> However, attempts should be made to isolate virus from the cerebrospinal fluid in cases of JE, WN, and other suspected flavivirus encephalitides in 1- to 3-day-old mice by intracerebral inoculation, or in cell culture such as Vero (African green monkey kidney) cells. Infected mice become sick and die in 3 to 10 days, and cell culture shows cytopathic effect during a similar period, indicating the possible presence of an infectious agent that can be identified antigenically. Isolation of virus from cerebrospinal fluid signifies a poor prognosis.<sup>3</sup> A serologic diagnosis can be made by showing a fourfold rise or fall in IgM and/or IgG antibody titer between acute serum and a convalescent sample collected one or two weeks after the onset of illness by neutralization, hemagglutination inhibition, immunofluorescence, or enzyme-linked immunosorbent assay (ELISA). The IgM capture ELISA is especially useful because flavivirus-specific IgM is usually present at the time the patient seeks care for encephalitis; antibody can be detected both in the serum and the cerebrospinal fluid.<sup>45,46</sup> IgM capture ELISA detection of antibodies on a single specimen generally indicates a recent infection, usually within the prior 6 weeks. In case of a negative IgM capture ELISA, a second test should be done a week later. However, caution must be exercised in the interpretation of IgM antibody results for WN infection because IgM antibody may persist in the serum for longer than 500 days.<sup>47</sup> Therefore, detection of IgM antibody in a single sample or in the absence of a rise in titer may be unrelated to the current illness. The cerebrospinal fluid IgM is oligoclonal and relatively specific and produces a stronger ELISA optical density signal than that of serum antibody. Diagnosis can also be established by virus isolation or by immunostaining of brain collected at biopsy or postmortem examination. The differential diagnosis includes other viral encephalitides caused by entero-, herpes-, alpha-, and rabies viruses, as well as tuberculosis, cerebral malaria, cerebrovascular accidents, toxins, and rickettsial infections.

Interpretation of serologic results is complicated by flavivirus cross-reacting antibody.<sup>48</sup> A second flavivirus infection leads to an anamnestic response that is characterized by the rapid development of antibody that is so cross-reactive among flaviviruses that it may not be possible to determine the specific infecting flavivirus.<sup>49</sup> In fact, the antibody titer to the first infecting flavivirus may be higher than the titer of antibodies to the more recent agent. Attempts to isolate virus from these patients is often unsuccessful. The use of reverse transcription-polymerase chain reaction (RT-PCR) to detect flavivirus RNA<sup>50</sup> employs consensus primers to amplify conserved regions of

the genome. As a second step, primers specific for each flavivirus are used, and the resulting complementary DNA (cDNA) can be sequenced or detected by DNA-DNA hybridization. This technique is highly specific and can be completed in 1 or 2 days.

## TREATMENT AND PROGNOSIS

Treatment is nonspecific and supportive for WN and JE infections. Supportive treatment of encephalitis cases includes intravenous fluid, electrolyte management, assisted respiration if needed, anticonvulsants, management of cerebral edema, prevention of secondary bacterial infections, and nursing care.<sup>22,51</sup> Physical and psychological rehabilitation is important in surviving patients, because sequelae are common and can result in major disability. Studies have assessed ribavirin, interferon, osmotic agents, gamma globulins, and steroids for treatment of WN in open trials, but more definitive evidence is needed to determine their efficacy, if any. For example, although interferon-alpha was shown to be the most promising treatment drug in small open trials for JE, a double-blind, placebo-controlled trial showed that it did not affect disease outcome in children.<sup>7</sup> Also, studies on WNV infection are being conducted, employing an open labeled-trial to assess the efficacy of interferon-alpha2b, and a placebo-controlled, double-blind, multicenter trial is being conducted to evaluate the efficacy of pooled human immunoglobulin for treatment of naturally occurring cases in the United States.<sup>52,53</sup> Interest in the use of anti-WNV human immunoglobulin has increased because open trials suggested that WN CNS infection was aborted in at least two human cases.<sup>52</sup> In addition, several studies showed varying degrees of efficacy for anti-WNV human immunoglobulin or mouse immune serum in mouse models of WNV infection.<sup>52</sup> However, the relevance of these animal studies for the prevention and/or treatment of human disease must be interpreted with caution.

Some of the risk factors predictive of a poor outcome and possibly death for WN neurologic cases include profound weakness, deep coma, lack of production of IgM antibody, immunosuppression, diabetes, and hypertension. Neurologic sequelae are common; for example, in one study in the United States, half of the patients had functional deficit when discharged from the hospital, and only one-third had fully recovered after one year. More recent findings indicate that the frequency and type of seizures and status epilepticus are important predictors of a poor outcome of JE in children.<sup>54</sup> Importantly, in many children, subtle motor seizures, such as twitching of a digit or eyebrow, were the only signs of status epilepticus that could be confirmed by electroencephalography. Awareness, appropriate attention, and management of these manifestations may lead to a better outcome.

## PREVENTION AND CONTROL

### Japanese Encephalitis Virus

A formalin-inactivated JE vaccine is licensed for human use in the United States and in countries of Asia. It is safe, efficacious, and has been available for many years, but is too expensive for use in most Asian countries.<sup>11</sup> In the United States it is used primarily for military personnel and tourists

visiting Asia. This vaccine is produced in Japan, Taiwan, Korea, and Thailand in adult mouse brain and is purified by protamine sulfate precipitation and ultracentrifugation to remove myelin basic protein. In Japan (one of the main suppliers to the Western market), manufacture of this mouse-brain derived vaccine is currently being replaced with a Vero-cell derived vaccine. Vaccine made with the Beijing-1 strain of JE virus is distributed in Japan and Asia, and another vaccine made in Japan with the Nakayama strain is produced for export to the United States and Europe. A field trial in Thailand demonstrated greater than 91% efficacy after two inoculations.<sup>11</sup> Vaccination of U.S. nationals showed that three inoculations more effectively induced neutralizing antibodies than two.<sup>55</sup> Although no serious side effects were noted in the trials, some late-onset hypersensitivity reactions have been observed since. Currently, three inoculations are recommended in the United States.<sup>56</sup>

A JE formalin-inactivated vaccine is produced in China in primary hamster kidney cells.<sup>57</sup> This inexpensive vaccine has been used for decades to immunize school children, but is not available outside of China. A JE formalin-inactivated vaccine produced in Vero cells is undergoing phase III clinical trials in Japan and is likely to replace the mouse-brain derived vaccine in the near future. More recently, the SA14-14-2 live attenuated JE vaccine, produced by serial passage in mice, hamsters, and primary hamster kidney cell culture, has been widely used in China. Efficacy is 80% after one dose, but antibody wanes rapidly, and a booster dose at 12 months is recommended to achieve effective protection of 97.5% of recipients.<sup>58</sup> However when administered just before the start of the JE season, the efficacy of a single dose of vaccine was 99%.<sup>59</sup> Until recently, the use of this vaccine outside of China has been restricted by regulatory concerns over its production. The World Health Organization has recently described guidelines for the production of live attenuated JE vaccines, which will facilitate SA14-14-2's wider use in the future. The SA14-14-2 vaccine is undergoing further clinical trials in Korea.

Among the more promising novel JE candidates is a live attenuated vaccine, ChimeriVax-JE, which was prepared by replacing the prM-E genes of yellow fever 17D vaccine with the corresponding JE virus genes.<sup>60</sup> A recently completed randomized, double-blind, placebo-controlled phase II clinical trial showed that the vaccine was well tolerated with no adverse side effects.<sup>61</sup> In addition, the vaccine elicited high neutralizing antibody in more than 90% of the 87 volunteers within 30 days following a single inoculation of a range of doses. If further clinical trials are successful, this vaccine offers an advantage over inactivated vaccines that require multiple doses.

While the control of JE can be achieved by vaccination of humans,<sup>62</sup> vaccination will not interrupt the transmission cycles in nature. Therefore, an effective live attenuated vaccine was developed to immunize pigs, the amplifying host of JE virus.<sup>63</sup> These vaccines, however, have met with limited success for at least three reasons. Farmers are not prone to invest in public health, pigs in Japan are marketed at less than 1 year of age, which presents a limited window of time for immunization, and the numbers of pigs are so great that the cost of annual vaccinations is prohibitive.

Until a vaccine is available that can be administered to those at greatest risk, such as children, efforts should be made

to avoid exposure to the vector mosquitoes during hours of biting or to use repellants. Vector control measures should be targeted at immature and adult vector species using larvacides and adulticides. Also, swine should be vaccinated or housed away from living quarters.

### West Nile Virus

The rapidly growing global threat of WNV to human and animal health has led to numerous studies aimed at the development of vaccines using both traditional and novel approaches.<sup>64</sup> Veterinary vaccine development has targeted protecting equines and other domestic animals. In the United States, a formalin-inactivated vaccine was licensed for equines during 2002, and an inactivated vaccine that protected mice, geese, and equines against a lethal challenge was approved for veterinary use during 2004 in Israel. A canarypox-vectored vaccine with *prM* and *E* genes of WNV has recently been licensed in the United States for use in equines.<sup>23</sup> Several candidate vaccines for humans have been developed and are under evaluation. These include a recombinant subunit vaccine derived by expressing WNV *E* protein in transfected insect cells that protected hamsters from lethal challenge with WNV.<sup>65</sup> Also, a subunit vaccine derived by expressing the WNV *E* protein fused to maltose-binding protein in *Escherichia coli* induced antibody and protected mice from challenge with 10 plaque-forming units of virus, but not from higher challenge doses.<sup>64</sup> A DNA vaccine is under development that utilizes the optimal signal sequence from JEV for the processing of *prM* and *E* proteins to produce viral-like particles is under development. This vaccine candidate has been shown to induce antibody that protects mice and equines.<sup>64</sup> Among several attenuated vaccines under development, a live yellow fever virus–WN (WN-YF) chimera induced antibody that protects mice, hamsters, and monkeys against a lethal challenge with WNV.<sup>25,66</sup> Furthermore, the NIH has developed a live dengue virus–WN (DEN-WNV) chimera that protects mice and monkeys against a virulent strain of WNV.<sup>64</sup> Other strategies for developing WN vaccines include a DNA construct that produces infectious Kunjin virus in vivo capable of inducing antibody that protects mice against a lethal challenge of a New York strain of WNV.<sup>64</sup> Studies conducted to evaluate cross-protection against WNV induced by heterologous flaviviruses have also shown promising results.<sup>64</sup> While all of these preclinical studies are promising, the public health utility will depend on the eventual outcome of safety and efficacy trials that will need to be conducted in human volunteers for consideration of approval and selection for large-scale manufacture and distribution.

While a safe and effective vaccine is needed, it is not likely that vaccination of a large component of the population will be feasible and cost effective. Therefore, an effective therapeutic agent is needed for treatment of WN viral infection among those at an increased risk of severe disease, such as the immunocompromised and the elderly.<sup>21</sup>

In the meantime, until vaccines are available, any efforts to prevent WN disease should be targeted at reducing the risk to humans exposed to infected mosquitoes by using personal protective measures and by instituting appropriate surveillance and vector control measures.<sup>67</sup>

### Other Flaviviruses

MVE virus, also closely related to the JE and WN viruses, is limited to Australia where it causes severe encephalitis and is maintained by *Culex* mosquitoes in the resident bird populations.<sup>68</sup>

Rocio virus is the cause of São Paulo encephalitis, a disease localized to the area near São Paulo, Brazil. A total of 971 cases were first recorded in 1975 in an explosive outbreak that continued through 1976.<sup>69</sup> A single additional fatal case was diagnosed serologically in 1980, and the disease has not been seen since. Clinically, the disease resembled St. Louis encephalitis, with about 20% of the patients having CNS sequelae and a mortality rate of 4% among hospitalized patients. The incidence during the 1975 outbreak was highest among young adult males involved in outdoor activities in agricultural areas. *Aedes* mosquitoes and wild birds were suspected as the reservoir on epidemiologic grounds. Since the initial outbreak, serologic evidence of Rocio infection in other parts of Brazil has been reported, and public health authorities are concerned about a return of Rocio outbreaks in Brazil.<sup>70</sup>

KFD virus is the cause of a hemorrhagic disease localized to six small forest foci in Karnataka state, India.<sup>71</sup> Since the disease was first recognized in 1957, about 400 to 500 cases have been reported each year, with a mortality rate of 3% to 5%. The virus belongs to the tick-borne encephalitis serocomplex. The cycle in the forest is maintained in *Haemaphysalis* ticks and small mammals and birds. KFD virus is readily isolated from monkeys that are often found sick or dead in the enzootic foci. KFD is clinically and virologically similar to Omsk hemorrhagic fever, a disease of the temperate regions of Omsk and Novosibirsk oblasts of Russia. The risk of infection is greatest among individuals who are in close contact with forested areas during the dry season. Clinically, patients present with a febrile syndrome accompanied by hemorrhages.<sup>72</sup> Some patients experience a biphasic course with signs of meningoencephalitis.

Zika virus has been diagnosed in 12 naturally acquired cases that occurred in Nigeria, Senegal, Central African Republic, and Indonesia.<sup>73</sup> Antibody prevalence of 50% or more in many African populations suggests that Zika virus infection is probably much more common than recognized. Patients have a self-limited disease characterized by fever, malaise, headache, and rash. The virus is maintained in a cycle involving *Aedes* mosquitoes and forest primates.

A formalin-inactivated vaccine for Kyasanur Forest disease (KFD) has been used in India.<sup>74</sup> There are no vaccines for St. Louis encephalitis, Murray Valley encephalitis (MVE), Rocio, and Ilheus viruses, and vaccines for these diseases are not likely to find commercial backing because of the small demand.

# Alphavirus Infections

SCOTT C. WEAVER  
ROBERT B. TESH  
ROBERT E. SHOPE

## INTRODUCTION

The alphaviruses comprise a genus (*Alphavirus*) in the family *Togaviridae* of enveloped, single-stranded, positive-sense RNA viruses that occur nearly worldwide<sup>1</sup> (Table 74-1). Alphaviruses are zoonotic pathogens that are maintained primarily in rodents, primates, and birds by mosquito vectors, although a few infect fish and seals and may have no arthropod vector. Human disease occurs when people intrude on enzootic transmission habitats and are bitten by infected mosquitoes, or when alphaviruses emerge to cause epizootics and epidemics. Five alphaviruses commonly infect people in the tropics and have epidemic potential: Venezuelan equine encephalitis (VEEV), chikungunya (CHIKV), Ross River (RRV), o'nyong-nyong (ONNV), and Mayaro (MAYV) viruses. Several other alphaviruses, including eastern and western equine encephalitis and Sindbis viruses cause human disease primarily in temperate regions and are therefore not discussed here.

## AGENT

### Alphavirus Structure and Replication

Alphavirus virions are about 70 nm in diameter and include an icosahedral nucleocapsid with T=4 symmetry surrounded by a host cell-derived lipid envelope containing glycoprotein spikes. The spikes are comprised of 240 heterodimers of the E1 and E2 envelope glycoproteins arranged in 80 trimers. The spike distribution is determined by interactions between the cytoplasmic tails of the E2 glycoproteins with capsid proteins. The E1 glycoprotein lies parallel to the lipid envelope while the E2 glycoprotein projects outward to form the spikes.

The alphavirus genome is a positive (messenger) sense, single-stranded RNA ca. 11,400–12,000 nucleotides in length (Fig. 74-1). Like cellular messenger RNA, alphavirus genomic RNA contains a 5' methylguanylate cap structure and 3' polyadenylate sequence. The nonstructural viral proteins coded by the 5' two-thirds of the genome are translated directly from this RNA upon entry into the cytoplasm. Structural proteins are encoded by a subgenomic RNA that is identical in sequence to the 3' one-third of the genome and is also capped and polyadenylated. Full-length, minus-strand RNA is synthesized from the genomic template and serves as a

template for both subgenomic and genomic RNAs. Minus-strand synthesis is favored early during viral replication while plus strand synthesis predominates later. This strand preference is regulated by the sequential processing of the nonstructural proteins, which are initially synthesized as two polypeptides nsP123 and nsP1234, or as a single nsP1234 that favors minus strand synthesis (some alphaviruses contain a terminating codon between nsP3 and nsP4, and others contain arginine or cysteine codons at this position) and later are cleaved into individual proteins that favor plus strand synthesis. The processing of the nsP polyproteins is mediated by a protease domain of nsP2.

The functions of the nonstructural proteins are not completely understood. nsP1 serves as a guanine-7-methyltransferase and a guanylttransferase for capping of both genomic and subgenomic RNAs and is involved in binding of replicative complexes to the cytoplasmic membranes. The N-terminal domain of nsP2 has helicase function, and the C-terminus is a protease that regulates processing of nonstructural proteins. nsP3 also appears to be involved in the functioning of the subgenomic promoter, is transported to the nucleus, and affects cytopathology in some vertebrate cells. nsP3 is the least understood protein and is poorly conserved among alphaviruses. nsP4 is the RNA-dependent RNA polymerase for both minus- and plus-strand RNA synthesis.

Alphavirus genomes contain several conserved RNA sequences, called cis-acting elements (CSE), that are required for replication. These include: (1) a 19-nt CSE that immediately precedes the 3' terminal poly(A) tract and is an important promoter element for minus-strand RNA synthesis; (2) a 24-nt CSE that serves as a promoter for the subgenomic RNA. The 5' terminus that contains at least two functional elements: (3) a 51-nt CSE (ca nt 155–205) located within the nsP1 coding sequence that is predicted to form two short stem-loop structures, and which functions as a replicational enhancer; and (4) the 5' untranslated region that contains a promoter (on the complementary strand) for initiation of the plus-strand RNA synthesis. The 5' and 3' ends of alphavirus genomic RNAs probably interact with the help of translation initiation factors to initiate replication.

Alphavirus structural proteins are translated from the subgenomic RNA as a single polypeptide that is cleaved co- and post-translationally. The capsid protein, synthesized first, possesses serine protease activity and cleaves itself from the polypeptide chain immediately following its translation. The E3 and E2 proteins (called PE2 or P62 before their cleavage) are translocated into the endoplasmic reticulum (ER), where they remain anchored to membranes via hydrophobic amino acids near the C-terminus. The C-terminal part of a small peptide called 6K serves as the signal peptide required for transport of the E1 envelope glycoprotein into the ER, where it is attached to membranes via a hydrophobic anchor on the C-terminus. Proteolytic cleavages between PE2, 6K, and E1 are performed by cell signalases. The E3/E2 cleavage is accomplished last by a furin-type protease and is generally required for viral infectivity. During transport to the cell surface via the secretory pathway, the envelope proteins are post-translationally modified via glycosylation, palmitoylation, and heterodimerization.

For virion assembly, the capsid protein recognizes an encapsidation signal(s) generally located in the nonstructural

FIGURE 74-1 The alphavirus gene.

protein genes of the genomic RNA. This initiates nucleocapsid formation involving 240 molecules of the capsid protein to form an icosahedral particle in the cytoplasm. To complete virion assembly, the capsid protein molecules interact with the cytoplasmic domain of E2 in E1–E2 heterodimers on the plasma membrane, leading to a budding process whereby the nucleocapsid incorporates its envelope and glycoprotein spikes, and resulting in release of virus particles from the cell surface.

The glycoprotein spikes composed of E1/E2 heterodimers function both in attachment to cellular receptors and in fusion with endosomal membranes for entry into cells. The E2 glycoprotein includes the major antigenic determinants and probably interacts with cellular receptors, while the E1 protein includes the conserved fusion peptide and hemagglutination activity. The E2 glycoprotein has been shown to be an important determinant of alphavirus virulence and infectivity for mosquitoes. Many of the biologically important epitopes on the E1 and the E2 glycoproteins are conformational, making the design of subunit or peptide vaccines difficult. The C protein elicits broadly cross-reactive antibody and is also a major complement-fixing antigen.

Most alphaviruses infect a wide variety of hosts and cell lines of vertebrate and invertebrate origin. Several receptors have been identified and include highly conserved proteins such as the high affinity laminin receptor. However, multiple receptors and perhaps coreceptors probably explain the wide host range, especially for vertebrates, yet specificity that is sometimes exhibited for oral infection of mosquito vectors. The E2 protein interacts directly with cell receptors, and amino acids 180–220 probably comprise a major receptor-reactive domain. Alphaviruses enter cells via receptor-mediated

endocytosis followed by fusion with endosomal membranes following conformational changes in the glycoprotein spikes at acidic pH. A highly conserved peptide (amino acids 80–96) in the E1 glycoprotein is the putative fusion peptide. Fusion leads to the release of the nucleocapsid into the cytoplasm, followed by disassembly in association with ribosomes.

Alphavirus replication is accompanied by inhibition of cellular synthesis of protein, RNA, and DNA via poorly characterized mechanisms. However, the viral RNAs are translated very efficiently thanks to translational enhancers. Transcriptional shutoff may play an important role in the inhibition of interferon (IFN) production by infected cells and a more efficient dissemination of the infection. Apoptosis appears to be a major cause of death in alphavirus-infected cells.

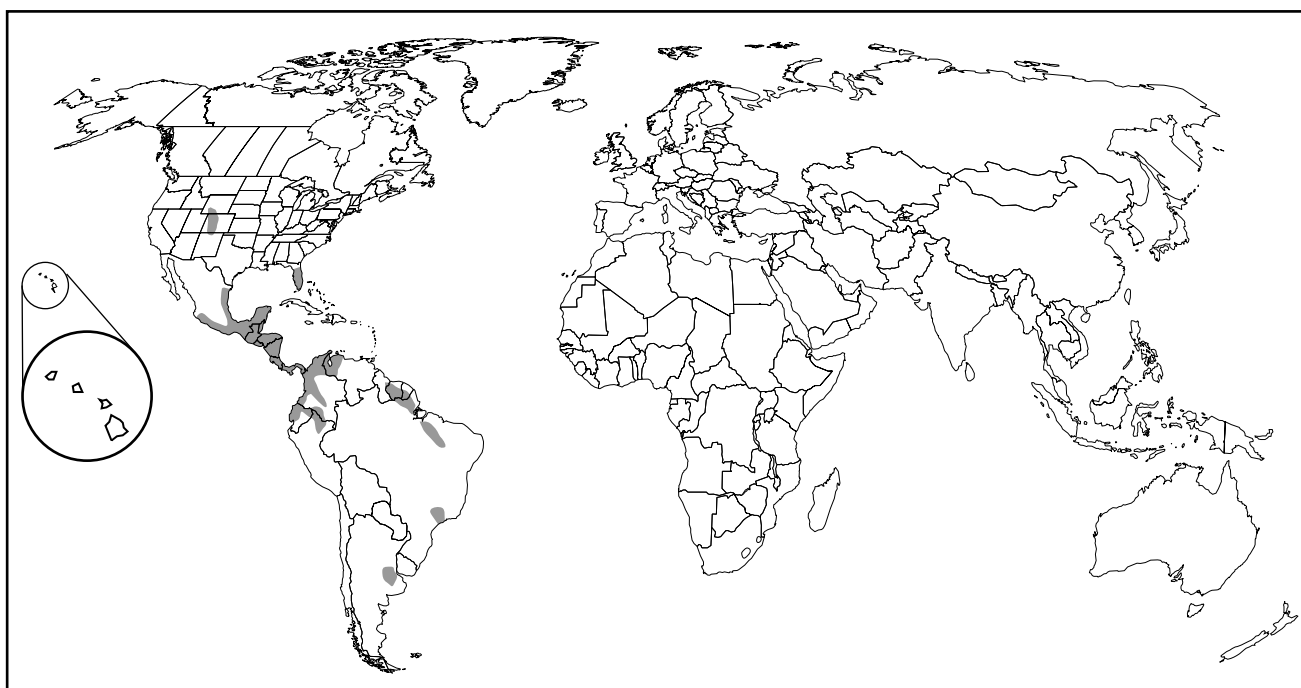

## EPIDEMIOLOGY

### Venezuelan Equine Encephalitis

VEE was first recognized in Venezuela in 1936 and has caused periodic equine epizootics and epidemics in many regions of tropical America.<sup>2</sup> A major epidemic in northern Venezuela and Colombia in 1995 involved approximately 100,000 persons.<sup>3,4</sup> VEE complex alphaviruses occur in two distinct transmission cycles: enzootic and epidemic (or epizootic). Enzootic cycles involving small mammalian hosts and mosquitoes in the subgenus *Culex* (*Melanoconion*) occur in tropical forest and swamp habitats in the New World ranging from Florida to Argentina (Fig. 74-2). Enzootic viruses (antigenic subtypes ID–F, II–VI) are generally avirulent for equines, but are pathogenic for humans and can cause

**FIGURE 74-2** The enzootic transmission cycles of Venezuelan equine encephalomyelitis complex viruses.

Venezuelan Equine Encephalomyelitis Complex

fatal disease.<sup>5,6</sup> In contrast, epidemic or epizootic VEEV (subtypes IAB, IC) are virulent for both equines and humans, but have no known interepizootic maintenance cycles. Epizootic transmission involves several species of mammalophilic mosquitoes, including *Ochlerotatus* (formerly *Aedes*) and *Psorophora*, which transmit the virus among equines circulating high levels of viremia (Fig. 74-3). People also become infected by mosquitoes that previously engorged on viremic equines.

**FIGURE 74-3** The epidemic and epizootic transmission cycle of Venezuelan equine encephalomyelitis viruses.

However, human-mosquito-human transmission is uncertain. During epizootics, equine fatality rates range from 30% to 80%. A large supply of susceptible equines and large numbers of mosquitoes, usually following heavy rainfall during the wet season, are prerequisites of epizootics. Most outbreaks have occurred in Venezuela, Colombia, Ecuador and Peru, although one spread from El Salvador through much of Central America, reaching Mexico and Texas in 1971. VEE outbreaks are believed to occur following mutations of enzootic subtype ID viruses that result in the transformation to an equine-virulent, IAB or IC phenotype.<sup>2</sup>

### Mayaro Virus

Mayaro virus was first isolated in 1954 in Trinidad from the blood of febrile forest workers.<sup>7</sup> Since then it has been isolated from sick people and mosquitoes in lowland tropical forests of Surinam, French Guiana, Colombia, Panama, Brazil, Peru, and Bolivia.<sup>8,9</sup> Mayaro infections usually occur in people living near or working in tropical forests; for this reason, most reported cases have been in adult males. Although the virus has been recovered from a variety of mosquitoes, forest-dwelling *Haemagogus* spp. are thought to be the principal vectors, and monkeys probably serve as reservoirs. Because of its sylvatic distribution, human infections with Mayaro virus usually occur as sporadic cases of febrile illness or small focal outbreaks. Mayaro activity is often detected during investigations of dengue or sylvatic yellow fever, the latter association probably explained by both viruses sharing the same enzootic mosquito vector. Because of its sporadic occurrence, rural distribution, and nonspecific nature, most cases of Mayaro fever are probably unrecognized or misdiagnosed.

## Ross River Virus

RRV infection, known as epidemic polyarthritis, occurs in Australia and the South Pacific. In Australia, disease occurs mainly during the summer and autumn as sporadic cases and small outbreaks, usually among vacationers and other persons traveling in rural areas; typically, several thousand Australian cases are reported annually. Ross River virus is thought to be maintained in Australia primarily in a wild vertebrate-mosquito cycle, with *Culex annulirostris* and *Aedes vigilax* serving as the principal vectors.<sup>10</sup> Human infection also occurs in Papua, New Guinea, the Solomon Islands, New Caledonia, Fiji, American Samoa, and the Cook Islands.<sup>11</sup> During 1979 and 1980, a large, explosive epidemic of Ross River polyarthritis swept across the South Pacific, with 40% to 60% of the population affected within a few months on some islands.<sup>10</sup> Epidemiologic studies during these outbreaks implicated *Aedes polynesiensis* as the vector and suggested a human-mosquito-human transmission cycle.<sup>10-12</sup>

## Chikungunya Virus

CHIKV was first isolated during a 1952 epidemic in Tanzania.<sup>13</sup> *Chikungunya* comes from Swahili, meaning “that which bends up,” and refers to the characteristic posture assumed by patients typically suffering severe joint pains. Carey<sup>14</sup> presented convincing historical evidence that CHIK has occurred sporadically in India and Southeast Asia for at least 200 years. The known geographic distribution of the virus includes most of sub-Saharan Africa, India, Southeast Asia, Indonesia, and the Philippines.<sup>10,11</sup>

There appear to be two distinct transmission cycles for CHIKV: (1) a sylvatic African cycle between wild primates and arboreal *Aedes* mosquitoes,<sup>15,16</sup> similar to that of sylvatic yellow fever virus in the same region; and (2) urban CHIK outbreaks associated with *Aedes aegypti* transmission in a human-mosquito-human cycle.<sup>10,15</sup> Urban outbreaks of CHIK are sporadic in occurrence but explosive. During the past 40 years, extensive epidemics have occurred in many large cities of India and Southeast Asia, sometimes affecting hundreds of thousands of people. Occasionally, epidemics of dengue and CHIK have occurred simultaneously in the same community, making clinical differentiation of the two diseases difficult. However, unlike dengue which has become endemic in many urban centers in tropical Asia, CHIKV disappears and reappears at irregular intervals.<sup>15</sup> The mechanism of virus survival during interepidemic periods is unknown.

## O'nyong-nyong Virus

The epidemiology of ONNV remains poorly understood 45 years after its discovery in East Africa. Its name is derived from the description by the Acholi tribe, meaning “joint breaker.”<sup>10</sup> The virus was first isolated during a 1959–1962 epidemic involving about 2 million people in Uganda, Kenya, Tanzania, Mozambique, Malawi, and Senegal. Attack rates were high and all age groups were infected.<sup>10</sup> An antigenically closely related virus, Igbo-Ora, was later isolated from febrile patients in Nigeria. Igbo-Ora virus is now considered a variant of ONNV, which is closely related but evolutionarily distinct from CHIKV.<sup>17</sup> The transmission cycle of ONNV

involves *Anopheles funestus* and *An. gambiae* mosquitoes; ONNV is the only known alphavirus and one of few arboviruses to use *Anopheles* vectors. In June 1996, a new outbreak of ONNV infection began in the Rakai district of southwestern Uganda.<sup>18</sup> The epidemic later spread into the neighboring Mbarara and Masaka districts of Uganda, and the bordering Bukoba district of northern Tanzania, with estimated attack rates of 29%–41%.

## DISEASES

### Venezuelan Equine Encephalitis

Human VEEV infection causes a disease spectrum ranging from inapparent infection to acute encephalitis, with attack rates of about 30%.<sup>4</sup> Following an incubation period of 1 to 4 days, signs and symptoms typically include fever, lethargy, headache, chills, dizziness, body aches, nausea, vomiting, and prostration.<sup>19</sup> Inflammation of the throat, cervical lymphadenitis, and abdominal tenderness are also common.<sup>20,21</sup> Symptoms usually subside after several days, but may recrudesce. VEE occurs in all age groups and both sexes. Severe neurologic signs, including seizures occur in 4% to 14% of cases, primarily in children, and often late in the illness. Case fatality rates in patients that develop encephalitis have been estimated at 10% to 25%.<sup>19,21,22</sup> Laboratory findings include leukopenia, with lymphopenia during the first few days of illness, followed by a lymphocyte rebound and neutrophil decline. White blood cells, predominantly lymphocytes, have been reported from the cerebrospinal fluid (CSF). CSF protein is occasionally slightly elevated, along with serum aspartate transaminase.<sup>21</sup>

### Mayaro Fever

MAYV infection is characterized by a sudden onset of fever, chills, headache, eye pain, generalized myalgia, arthralgia, diarrhea, vomiting, and rash of 3–5 days' duration.<sup>8,9</sup> The arthralgia associated with Mayaro fever may be severe and usually affects the wrists, ankles, and toes, and less commonly the elbows and knees. In some cases, arthralgia is accompanied by swollen joints and can be incapacitating, persisting for up to two months.<sup>19</sup> The disease is self-limiting; systemic symptoms usually last from 2 to 5 days. Approximately two-thirds of patients develop a fine maculopapular rash on the trunk and extremities, appearing about the fifth day of illness and lasting about three days. Leukopenia, with moderate lymphocytosis, occurs in most patients during the first week of illness. Platelet counts and liver function tests are usually within normal limits.

### Ross River Virus Infection

The reported incubation period ranges from 3 to 21 days (mean, 9 days), and disease begins suddenly with headache, malaise, myalgia, and joint pain.<sup>12,23</sup> Multiple joints are involved, most commonly the ankles, fingers, knees, and wrists. Pain and loss of function usually last for several weeks, but some patients have persistent or recurrent arthralgia and arthritis for up to a year. About half of patients develop a maculopapular rash, usually lasting 5 to 10 days; 30% to 50%

also have low-grade fever. Persons 20 to 50 years of age are most commonly affected, and the incidence is higher in females. Viremia is transient and may precede the onset of arthritis. The skin rash and joint swelling appear to be due to a local cell-mediated immune response rather than to immune complexes or complement-mediated reaction.<sup>12</sup> The synovial exudate contains no detectable virus and consists almost entirely of mononuclear leukocytes.

### Chikungunya Virus Infection

CHIKV infection is characterized by the sudden onset of fever, chills, headache, photophobia, backache, nausea, vomiting, arthralgia, and rash. Patients are quite sick, although the acute illness only lasts about 3 to 5 days, with recovery usually in 5 to 7 days.<sup>15</sup> The incubation period is about 2 to 4 days, and the most common complaint is the severe arthralgia, which is seen in 70% of cases. Single or multiple joints may be involved, with swelling and reddening common. As with RRV and MAYV infections, some patients have persistent or recurrent joint pain and stiffness for a year or more. The rash associated with CHIKV is maculopapular and mainly involves the trunk. Febrile convulsions sometimes occur in children, and hemorrhagic manifestations (petechiae, purpura, epistaxis, bleeding gums, hematemesis, and melena) also have been reported.<sup>24</sup> Biopsies from skin lesions of CHIKV patients show perivascular lymphocytic infiltrate in the upper dermis, and red blood cell extravasation is seen around the superficial capillaries.<sup>15</sup>

### O'nyong-nyong Infection

Disease due to ONNV infection is clinically indistinguishable from CHIKV, including fever, joint pains, rash, and lymphadenitis.<sup>10</sup>

## PATHOGENESIS AND IMMUNITY

In vertebrates, initial sites of alphavirus replication include skeletal muscle and Langerhans cells in the skin, leading to infection of the draining lymph node. Plasma viremia probably is the main form of dissemination to other tissues and organs. Some Old World alphaviruses that cause a rash replicate in the skin and in striated muscle. Infection of macrophages may mediate the pathology in some infections that lead to an arthritic syndrome. Invasion of the central nervous system by the encephalitic alphaviruses generally follows initial virus replication in various peripheral sites and a period of viremia exceeding a threshold for CNS entry. Entry to the CNS through the olfactory tract has been demonstrated for Venezuelan equine encephalitis virus in a mouse model, but has not been investigated for most alphaviruses, and pathogenesis in humans is very poorly understood. CNS invasion may also occur through endothelial cells or via infected monocytic cells in the blood. In mosquito vectors, alphaviruses generally infect via a viremic blood meal by first infecting and replicating in posterior midgut epithelial cells. Dissemination into the hemocoel then results in infection of secondary target organs including the salivary glands. Transmission via infectious saliva can then occur within a few days of mosquito infection when a subsequent blood meal is taken from a susceptible vertebrate host. Alphaviruses can also cause pathology in their mosquito vectors, though vector

pathogenesis has only been investigated thoroughly in a few cases. Cytopathic effects have been detected in the midgut, muscles, and salivary glands of mosquitoes.

Types I and II interferon are induced soon after alphavirus infections, and most studies indicate a greater role in protection against disease by Type I. Interferon type I appears to limit alphavirus replication during the early stages of infection before acquired immunity becomes effective. Interferons and other cytokines may also contribute to alphaviral disease by causing a shock-like syndrome. Alphaviruses are highly immunogenic for vertebrates, but some can also be immunosuppressive. Although humoral immunity is believed to be more important for protection, both cellular and humoral immune mechanisms contribute to recovery following infection. IgM is usually elicited within 7–10 days of infection and persists for several months. IgG is first detected within a few weeks of infection and remains at least for years and probably for life following many infections.

## DIAGNOSIS

Definitive diagnosis of alphavirus infections generally requires virus isolation or serologic confirmation.<sup>19</sup> Alphaviruses can usually be recovered from blood taken during the first 2 to 4 days of illness; most alphaviruses readily kill newborn mice after intracerebral inoculation, and produce cytopathic effect in a variety of mammalian and avian cell lines. Seroconversion can also be demonstrated in acute and convalescent serum samples drawn 1 to 3 weeks apart. Rapid diagnosis can be achieved using virus-specific IgM capture enzyme-linked immunosorbent assay (ELISA). Although a variety of serologic tests can be used to detect alphavirus antibodies (ELISA, immunofluorescence, hemagglutination inhibition, and neutralization), many laboratories do not include these agents routinely in their diagnostic workup.

### Venezuelan Equine Encephalitis

In the absence of neurologic disease (most cases), clinical diagnosis of VEE is difficult because symptoms are indistinguishable from other tropical viral infections occurring in the same New World regions. The absence of rash and joint pain argue against a diagnosis of Mayaro or dengue fever. The identification of a major, ongoing equine encephalitis epizootic, not known to occur for these other viral agents, should raise suspicion of VEE.

Definitive diagnosis of VEE by virus isolation from serum is most successful during the first three days of illness, with titers of  $10^3$  to  $10^6$  plaque-forming units/mL typical.<sup>3</sup> Lower isolation rates are obtained from pharyngeal swabs. Reverse-transcription polymerase chain reaction assays have also been used to detect VEEV in human serum and throat swabs.<sup>3</sup> Identification of VEEV serotypes is best achieved using monoclonal antibodies and ELISA.<sup>25</sup> Phylogenetic studies have recently been used to delineate the source of outbreaks.<sup>2</sup>

### Mayaro Virus Infection

A clinical diagnosis of MAYV infection is difficult because of its nonspecific nature. The triad of fever, arthralgia, and rash occurs in most cases, but is shared with other viral and

bacterial illnesses. For example, Mayaro fever can easily be confused with dengue, which is often endemic or epidemic in the same regions of tropical America.<sup>9</sup>

### Ross River Virus Infection

RRV can be isolated from the serum of patients during the first 2 to 3 days of illness. Owing to the irregular onset of symptoms and relatively benign nature of the illness, many patients already have detectable circulating antibodies by the time they seek medical care. Inoculation of acute-phase serum into mosquitoes or mosquito cell cultures appears to be the most efficient method of RRV isolation.<sup>12</sup> A serologic diagnosis can also be made by detecting RRV-specific IgM or by demonstrating seroconversion or a rise in antibody titer between acute and convalescent paired sera.

### Chikungunya Virus Infection

Because of its frequent urban distribution, CHIKV infection can easily be mistaken for dengue, which is endemic in most urban areas of tropical Asia and Africa. It also can be confused with West Nile virus infection. During the acute febrile period, CHIKV is relatively easy to recover from a patient's blood. There is some antigenic cross-reaction in serologic tests between CHIKV, RRV, MAYV, Sindbis, and ONNV, and clinical features of the diseases caused by these alphaviruses are very similar.<sup>11</sup>

### O'nyong-nyong Infection

Diagnosis of ONN relies on the same criteria as CHIK, and serologic differentiation of the two infections can be difficult due to antigenic cross-reactivity and their sympatric distribution.<sup>10</sup> The combination of fever, arthralgia, and lymphadenopathy has a specificity of 83% and a sensitivity of 61% in the identification of ONN cases during epidemics.<sup>18</sup> ONNV can be readily isolated from serum during the first 6 days after onset, although some strains do not kill newborn mice.

## TREATMENT AND PROGNOSIS

### Venezuelan Equine Encephalitis

Treatment is symptomatic and supportive.<sup>19</sup> Anticonvulsive therapy may be useful in severe cases, especially in children. Lymphoid depletion may lead to bacterial infection of the gastrointestinal tract, and antibiotic treatment should be considered in severe cases. Secondary pneumonia is also common. Neurologic sequelae are common following severe VEE and include headache, forgetfulness, nervousness, and motor impairment.<sup>2,4,19–21</sup>

### Mayaro Fever

Treatment is symptomatic, and no fatalities have been reported.

### Ross River Virus Infection

Infection is self-limited and no fatalities have been reported; however, continuous or recurrent joint symptoms

can persist for up to one year. One patient with Ross River virus infection has developed transient neurologic symptoms.<sup>12</sup> Treatment is symptomatic.

### Chikungunya Virus Infection

Treatment is symptomatic and includes antipyretic and anti-inflammatory drugs. Aspirin should be avoided because of reports of mild hemorrhagic manifestations. Although the joint symptoms may persist for months, CHIK is generally an acute, self-limited infection with no deaths reported.

### O'nyong-nyong Infection

As with CHIK, ONN infection is self-limited and is treated symptomatically.

## PREVENTION AND CONTROL

No licensed human vaccines are available for alphaviruses, and control generally relies on interruption of transmission cycles by vector control and personal protection against vector bites using repellents containing the active ingredient diethyltoluamide (DEET) and by limiting outdoor activities.

### Venezuelan Equine Encephalitis

Vector control usually relies on aerial application of insecticides such as malathion, optimally applied soon after flood-water species emerge from the aquatic immature stages, prior to dispersal, infection, and incubation required for transmission.<sup>2,19,22</sup> Vaccination of equine amplification hosts relies on the TC-83 live attenuated strain, and "barriers" of immunized equines may control the spread of outbreaks. People present during epidemics or entering sylvatic habitats where enzootic VEEV circulates should avoid exposure to mosquitoes.

### Mayaro Fever

Control of MAYV infection is difficult because personal protective measures such as insect repellents and heavy clothing are not practical options for people who live and work continuously in humid tropical forests. Since *Haemagogus* spp. mosquitoes are mainly sylvatic and bite during the day, bed nets and window screens are not very effective.

### Ross River Virus Infection

Prevention relies on avoiding mosquito bites when traveling in rural areas where RRV circulates.

### Chikungunya Virus Infection

Control measures consist of avoidance of mosquito bites and vector control.

### O'nyong-nyong Infection

Prevention and control are limited to reductions of *Anopheles* vector populations and vector avoidance. Because *Anopheles*

mosquitoes usually bite at night, these include measures effective in preventing malaria infection, such as bed netting impregnated with permethrin and application of repellents when outdoor night-time exposure is anticipated.

# Rabies

THOMAS P. BLECK

## INTRODUCTION

Rabies is a viral disease producing an almost uniformly fatal encephalitis in humans and other mammals.<sup>1</sup> It has been known throughout recorded history and stands apart as the most nearly uniformly fatal of all viruses. Rabies remains one of the most common viral causes of mortality in tropical countries.<sup>2</sup>

Exposure to potentially rabid animals has profound economic and medical implications; about 4 million people receive postexposure treatment (PET) annually to prevent rabies.<sup>3</sup> Despite technology that permits the production of safe agents for PET, economic considerations frequently lead to the use of older, more dangerous vaccines in the developing world, with catastrophic neurologic complications as a result.

*Rabies* comes from the Latin *rabere*, to rage. Rabies is also related to the Sanskrit word for violence, *rabhas*. The Greek term for rabies, *lyssa*, madness, is the source of the taxonomic name of the viral genus, *Lyssavirus*. The Babylon Eshnuna code (23rd century BCE) probably contains the first mention of rabies.<sup>4,5</sup> The Greek philosopher Democritus provided the first clear description of animal rabies in about 500 BCE. Wound cauterization was mentioned in the first century CE and remained the only real treatment until Pasteur introduced immunization in 1885. St. Hubert, a medieval European healing saint, is depicted with a large key that was heated and used for cautery. In the twelfth century, Maimonides advised thorough wound cleansing, suction, cautery, and rest. Wound cautery remained part of most suggestions for potentially rabid animal bites into the middle of the 20th century.

The diagnosis of rabies was purely clinical until 1903, when Adelchi Negri described cytoplasmic inclusions (Negri bodies) in this disorder.<sup>6</sup> He initially thought that the inclusion body was part of the life cycle of a parasite.<sup>7</sup> This was the only pathologic marker until the introduction of fluorescent antibody techniques for rabies in 1958.<sup>8</sup>

## AGENT

The family Rhabdoviridae are negatively stranded RNA viruses consisting of two genera that infect animals (*Lyssavirus* and *Vesiculovirus*) and the plant rhabdovirus group.<sup>9</sup> The type species of the subfamily Lyssaviridae is rabies (serotype 1),<sup>10</sup> and that of the subfamily Vesiculoviridae is vesicular stomatitis virus. Rabies is enzootic, and sometimes epizootic,

in many mammals, most commonly wild and domestic canids (e.g., dogs, foxes, coyotes), mustelids (e.g., skunks, badgers, martens), viverrids (e.g., mongooses, civets, genets), procyonids (e.g., raccoons and their allies), and insectivorous and hematophagous bats. The five other members of the *Lyssavirus* genus are rare causes of human disease (Table 75-1).

The rabies virus is bullet-shaped, with an average length of 180 nm (range, 130 to 200 nm) and an average diameter of 75 nm (range, 60 to 110 nm).<sup>11</sup> The complete virus contains a helical nucleocapsid with 30 to 35 coils with a length unwound between 4.2 and 4.6  $\mu$ m.<sup>12</sup> The nucleocapsid is enclosed in a 7.5- to 10-nm-thick lipoprotein envelope; from this envelope, glycoprotein (G protein) spikes project out another 10 nm. The spikes cover the entire surface of the virus except for part of the blunt end.

The rabies viral genome is a single negative strand of RNA weighing 4.6 MDa, and contains a sequence of 11,932 nucleotides.<sup>13</sup> This RNA encodes five genes, named N, NS (or M<sub>1</sub>), M (or M<sub>2</sub>), G, and L. The N nucleoprotein binds to the RNA and is probably involved in the control of viral RNA replication; it is a potential immunogen.<sup>14</sup> The purpose of the NS phosphoprotein is less clear, but it may control the L protein, which is the polymerase for replication.<sup>15,16</sup> The M (matrix) protein is the major structural protein and is probably located between the nucleocapsid and lipoprotein envelope<sup>17</sup>; its role is uncertain.<sup>11</sup> The G protein is involved in cell surface reception, and it is the only antigen that induces virus neutralizing antibodies. Variability in this protein accounts for serotypic differences among lyssaviruses,<sup>18</sup> and mutations at arginine 333 cause loss of virulence.<sup>19</sup> This arginine residue is required for G protein-mediated fusion of the viral envelope with neurons.<sup>20</sup> Molecular modifications of the G protein can increase its antigenicity<sup>21</sup> and may aid in the search for better vaccines.

The nicotinic acetylcholine receptor is an important viral binding site, but it is probably not the only one. Once bound to the receptor, receptor-mediated endocytosis allows the virus to enter the neuron. This forms a coated pit, which then fuses with a lysosome, where enzymes release the nucleocapsid into the cytosol.<sup>22</sup> Five messenger RNAs (mRNAs) for production of the viral proteins are transcribed, and a full-length, positively stranded RNA is produced as the template for the viral progeny.<sup>23</sup> The envelope forms from host cisternal membranes into which the G and M proteins are inserted.<sup>24</sup> In natural infections the virus accumulates in cytoplasmic cisterns from which it is released either by membrane fusion or dissolution of the cell.<sup>22</sup>

The virus does not tolerate pH below 3 or above 11, and it is inactivated by ultraviolet light, sunlight, desiccation, or exposure to formalin, phenol, ether, trypsin,  $\beta$ -propiolactone, and detergents.

## EPIDEMIOLOGY

### Human Rabies

Rabies occurs throughout the world except in Antarctica and a few island nations. In 1999 (the last year for which global data are available), 99 of 151 nations reported the presence of rabies.<sup>25</sup>

Table 75-1 Members of the Lyssavirus Genus

Virus	Serotype	Reservoir	Comments	Cross-Protection with Rabies Vaccine
Rabies	1	Found worldwide except for a few island nations, Australia, and Antarctica. The vast majority of human cases occur in areas of uncontrolled domestic dog rabies.		Not applicable
Lagos bat	2	Probably enzootic in fruit bats. At least 10 cases have been identified, including three in domestic animals, in Nigeria, South Africa, Zimbabwe, Central African Republic, Senegal, and Ethiopia. No reported human cases.	First isolated in 1956 from brains of Nigerian fruit bats. Some cases initially diagnosed as rabies, but displayed weak immunofluorescence and later distinguished by monoclonal antibody or nucleotide sequence analysis.	Marginal
Mokola	3	Probably an insectivore or rodent species. Cases identified in Nigeria, South Africa, Cameroon, Zimbabwe, Central African Republic, and Ethiopia. At least 19 known cases, including 11 domestic animals and 2 human cases.	First isolated from shrews in Nigeria in 1968.	None
Duvenhage	4	Probably insectivorous bats. Cases identified in South Africa, Zimbabwe, and Senegal. Four cases known, including one human death. No cases in domestic animals.	First identified in 1970 in a man with a rabies-like encephalitis in South Africa (virus named after the patient). Negri bodies were present, but immunofluorescent stains were negative.	Marginal
European bat lyssavirus 1 (EBLV1)	5	European insectivorous bats (probably <i>Eptesicus serotimus</i> ). Over 400 bat cases and one confirmed human death and another suspected. No known domestic animal cases.	Suspected as early as 1954 but not identified until 1985. Almost all cases are in the common European house bat.	Marginal
European bat lyssavirus 2 (EBLV2)	6	European insectivorous bats (probably <i>Myotis dasycneme</i> ). Five known cases, including one human death. No known domestic animal cases.	First identified in a Swiss bat biologist who died in Finland.	Marginal

Adapted from Rupprecht CE, Smith JS, Fekadu M, et al: The ascension of wildlife rabies: a cause for public health concern or intervention? *Emerg Infect Dis* 1:107–114, 1995.

The epidemiology of human rabies is that of animal rabies in the community.<sup>26</sup> In developing areas where canine rabies is common, most cases of human rabies result from dog bites. Conversely, rabid wild animals are usually responsible for human rabies in regions where dogs are vaccinated. The spectrum of animals implicated in rabies transmission to humans continues to expand.<sup>27</sup> Transmission via organ donation from a donor not known to have rabies underscores the need for a higher index of suspicion for rabies.<sup>28</sup>

In 1999, 1866 cases of human rabies were reported to the World Health Organization (WHO).<sup>25</sup> These reports represent a substantial underestimate of the worldwide incidence of the disease, which probably causes as many as 100,000 deaths annually. The methods used for the diagnosis of rabies and their corresponding validities vary considerably across the globe. In Africa and Asia, more than 85% of cases are diagnosed on clinical grounds alone, and the source of exposure is not reported for more than half of these. An estimated 4 million persons receive PET annually; the vast majority of these patients are treated with vaccine types carrying a substantial risk of neurologic complications.<sup>29</sup>

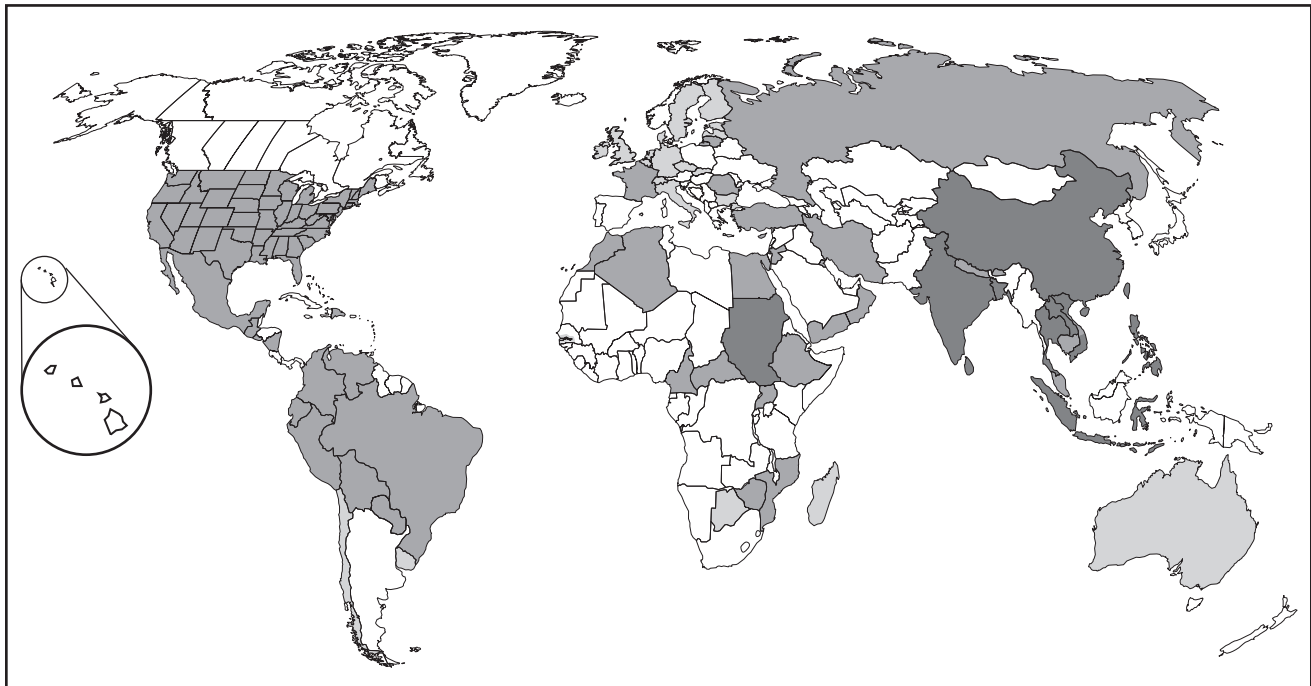

## Animal Rabies

Animal rabies throughout the world occurs in two types of clusters. In the developing world, rabies predominantly affects domestic or feral animals, with infection of wild animals less important in transmission of disease to humans. In more developed nations, animal control procedures have substantially eliminated rabies from domestic animal populations, and wild animals are the group most affected. For example, bat rabies is the most rapidly increasing source of human infections in the United States.<sup>30</sup> The relative susceptibilities of different animal species to rabies are shown in Table 75-2.

## PATHOLOGY

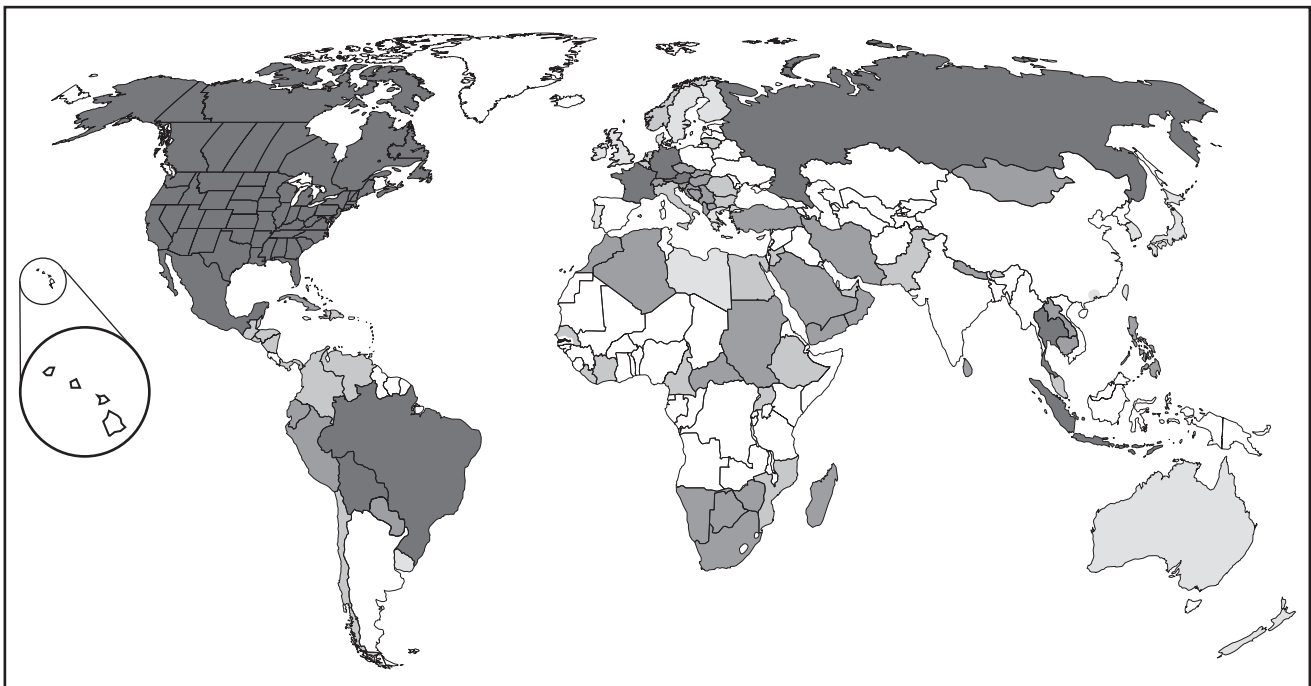

The appearance of the brain at autopsy is generally unremarkable,<sup>31</sup> except for the vascular congestion expected in patients dying after prolonged mechanical ventilation. The histologic study of rabies typically shows an encephalitis with Negri bodies. However, not all specimens show perivascular

### Human Rabies

lymphocytic cuffing and necrosis (which characterize encephalitis), and some cases have the histology of meningitis.<sup>32</sup>

Negri bodies are concentrated in hippocampal pyramidal cells and somewhat less frequently in cortical neurons (Fig. 75-1) and cerebellar Purkinje cells<sup>31</sup> (Fig. 75-2). These eosinophilic cytoplasmic inclusions are round or oval and measure between 1 and 7  $\mu\text{m}$  across. Immunofluorescent and ultrastructural analyses confirm that they contain rabies viral nucleocapsids.<sup>33</sup> The acidophilic lyssa body is ultrastructurally identical to the Negri body.<sup>34</sup>

Paralytic rabies expresses the majority of its pathologic changes in the spinal cord, with severe inflammation and neuronal necrosis<sup>35</sup>; the brain stem is less involved, and a minority of cases have cortical Negri bodies. Segmental demyelination of

peripheral nerves is common in these patients, which may explain the resemblance of paralytic rabies to acute inflammatory polyneuropathy (the Guillain-Barré syndrome).

The most important systemic finding in rabies is myocarditis, present in a large number of cases.<sup>36</sup> Its cause is uncertain, but it resembles the myocarditis of other hypercatecholaminergic states (e.g., pheochromocytoma, subarachnoid hemorrhage, and tetanus). However, the hearts of some patients demonstrate Negri bodies, suggesting a more direct pathogenic role for the virus.<sup>37</sup> The discovery of atrial ganglioneuritis suggests that the virus reaches the myocardium via spread from the nervous system.<sup>38</sup> Other postmortem findings reflect the complications commonly seen during a critical illness, such as upper gastrointestinal tract bleeding.

**FIGURE 75-1** Negri body in pyramidal neuron. (From Bleck TP, Rupprecht C: Rhabdoviruses. In Richman DD, Whitley RJ, Hayden FG [eds]: *Clinical Virology*, 2nd ed. Washington, DC, ASM Press, 2002, pp 857–873.)

## DISEASE

### Human Rabies

#### Transmission

Many variables affect the risk of rabies, as well as the incubation period, after exposure to a rabid animal.<sup>39</sup> The viral inoculum must play an important role, expressed in clinical practice as a relationship of rapidity with the extent of exposure to the saliva of a rabid animal (Table 75-3). Exposures in which large amounts of saliva contaminate a wound are more likely to produce rabies than a bite through thick clothing, which removes most of the saliva; and multiple bites are more likely to transmit the disease than a single one. The location of the bite is also an important determinant of the

likelihood of developing disease (e.g., bites on the face are more likely to produce disease than those on the extremities). Salivary contamination of a pre-existing wound, mucous membranes, or the respiratory tract (with aerosolized virus)<sup>40</sup> may also spread virus. Direct human-to-human transmission has been documented only in cases of transplants; one recipient was treated with standard PET plus interferon and did not become ill.<sup>37,41</sup>

#### Incubation

The reported incubation period varies from days to more than 19 years, with 75% of patients becoming ill within 90 days of exposure (Table 75-4).

**Table 75-3** Durations of Different Stages of Rabies

Stage	Type (% of Cases)	Duration (% of Cases)	Associated Findings
Incubation period		<30 days (25%) 30–90 days (50%) 90 days–1 yr (20%) >1 yr (5%)	None
Prodrome and early symptoms		2–10 days	Paresthesias or pain at wound site, fever, malaise, anorexia, nausea and vomiting
Acute neurologic disease	Furious rabies (80%)		Hallucinations, bizarre behavior, anxiety, agitation, biting, hydrophobia, autonomic dysfunction, syndrome of inappropriate antidiuretic hormone (SIADH)
Coma	Paralytic rabies (20%)	2–7 days	Ascending flaccid paralysis
Death*		0–14 days	

\*Rare recoveries have been reported.

Data from Fishbein DB: Rabies in humans. In Barr GM (ed): *The Natural History of Rabies*, 2nd ed. Boca Raton, Fla, CRC Press, 1991, pp 519–549.

**Table 75-4** Susceptibility of Various Animal Species to Rabies

Very High	High	Moderate	Low
Wolf	Hamster	Dog	Opossum
Fox	Skunk	Primate	
Coyote	Raccoon		
Kangaroo rat	Domestic cat		
Cotton rat	Rabbit		
Jackal	Bat		
Vole	Cattle		

Data from Sixth Report of the Expert Committee on Rabies. World Health Organ Tech Rep Ser 523, 1973.

### Prodrome

The initial symptoms of rabies resemble those of other systemic viral infections, including fever, headache, malaise, and upper respiratory and gastrointestinal tract disorders.<sup>42</sup> Neurologic problems include changes in personality and cognition, and paresthesias or pain near the exposure site. Because these complaints are so common, rabies is rarely considered early in the differential diagnosis. In one series, rabies was considered in only 3 of 21 patients during the first visit to a physician, despite an exposure history.<sup>42</sup> The prodrome usually lasts about 4 days, but as many as 10 days may elapse before more specific findings develop.<sup>39,43</sup> Myoedema (mounding of a part of the muscle struck with a reflex hammer) develops during the prodrome and persists thereafter.

### Established Disease

Human rabies is typically seen in two forms: *furious* and *paralytic* (or *dumb*). Furious rabies (80% of cases) is dominated by encephalitis and presents with hydrophobia, delirium, and agitation. Paralytic rabies shows little clinical evidence of cerebral cortical involvement until late. The pathologic distinction between these forms is primarily quantitative: the spinal cord and brain stem are more involved in the paralytic form. The reasons underlying the two types of rabies are unknown but do not appear to involve virologic or antigenic differences<sup>44</sup> or identified host factors.

Both forms of symptomatic rabies usually last between 2 and 14 days before the onset of coma, and death follows about 18 days after the onset, with a broad range described.<sup>42</sup> Critical care services prolong survival by about 50% but do not appear to change the outcome.<sup>45</sup>

**Furious Rabies.** Hydrophobia is the symptom most identified with furious rabies; it implies more than simple difficulty swallowing water and produces fear even of the sight of water despite strong thirst (Fig. 75-3). Hydrophobia probably represents an exaggerated irritant reflex of the respiratory tract, perhaps due to viral involvement of the nucleus ambiguus.<sup>46</sup> Other manifestations of the furious form include hyperactivity, seizures, and aerophobia. Hyperventilation is frequently present, presumably reflecting brain stem infection. When coma supervenes, pituitary dysfunction, especially disordered water balance (either inappropriate antidiuresis or diabetes insipidus), frequently develops. More serious forms

of ventilatory dysfunction replace hyperventilation, including periodic and ataxic respiration,<sup>46</sup> and eventually apnea may end the patient's struggles. Cardiac arrhythmias, mostly supraventricular tachycardias and bradycardias,<sup>47</sup> occur frequently, as a consequence of either brain stem dysfunction or myocarditis.<sup>48</sup> Other autonomic abnormalities include pupillary dilation, anisocoria, piloerection, increased salivation and sweating, and priapism,<sup>49</sup> including spontaneous ejaculation as well as erections.<sup>50</sup>

**FIGURE 75-3** Clinical features of furious rabies. A, The grimace and stare which accompany the pharyngeal spasms of hydrophobia. B, Aerophobia provoked by air movement across the patient's face. C, Inspiratory spasm. (From Hanley DF, Glass JD, McArthur JC, et al: Viral encephalitis and related conditions. In Bleck TP [ed]: Atlas of Infectious Diseases. Vol 3: Central Nervous System and Eye Infections. Mandell GL [series ed]. New York, Churchill Livingstone, 1995, p 3.28.)

Most furious rabies patients entering coma die within 1 to 2 weeks despite maximal supportive care. Those receiving maximal intensive care support and surviving for a longer-than-expected period pass through the paralytic phase prior to death.<sup>45</sup>

**Paralytic (Dumb) Rabies.** In contrast to furious rabies, paralytic rabies patients lack signs of cortical irritation (hydrophobia, aerophobia, hyperactivity, seizures). They may present with ascending paralysis or symmetrical tetraparesis. Weakness may be most severe in the exposed extremity. Headache and neck stiffness may be prominent despite a normal sensorium. As the condition progresses, the patient becomes confused and then comatose.

### Non-Neurologic Findings

In addition to the cardiac arrhythmias mentioned previously, the systemic complications of rabies are similar to those of other critically ill patients. Although the virus disseminates to many organs, its role in non-neurologic organ dysfunction is uncertain. Hypoxemia often develops and is frequently attributed to atelectasis, aspiration pneumonia, or congestive heart failure from myocarditis. Hypotension probably reflects volume depletion but may also follow brain stem involvement. Gastrointestinal complications, in addition to bleeding, include vomiting, diarrhea, and ileus.<sup>51</sup> Those who do not succumb to these complications usually die of rabies myocarditis, manifested as cardiac arrhythmia, or congestive heart failure.<sup>52</sup>

### Animal Rabies

WHO has established a ranking of animal rabies susceptibility (see Table 75-4).<sup>53</sup> Rabies in dogs and cats is similar to the human disease. Dogs display subtle behavioral changes during the prodromal phase, then enter an excitative (furious) phase; they are agitated, are restless, and may bite without provocation. Paralysis of laryngeal muscles produces a high-pitched bark.<sup>54</sup> Animals in the paralytic (dumb) phase display a “dropped jaw” from masseter weakness. Up to 24% of experimentally infected dogs in one study died without showing any signs of illness but were pathologically demonstrated to be rabid, making symptoms an unreliable guide to diagnosis.<sup>55</sup> The canine incubation period may last 8 months.<sup>56</sup> Other studies suggest that the incubation period depends on the inoculum and strain involved; experiments simulating natural infection suggest a period between 7 and 125 days,<sup>55</sup> and other experimental studies suggest that between 0% and 20% of infected dogs may recover without treatment.<sup>54</sup>

Cats have a 2- to 3-day prodrome, with subtle behavioral changes, slight fever, pupillary dilation, and impaired corneal reflexes. Most rabid cats then become furious, frequently scratching or biting without provocation. During the next 2 to 4 days, hypersalivation, tremor, and incoordination are common. Paralysis then ensues, and convulsions may develop; death usually follows in a few days. A description of behavioral changes in wild animals may be found in Baer.<sup>57</sup>

### PATHOGENESIS

Virus can enter both motor and sensory nerves. Murphy and colleagues first deciphered the pathogenesis of rabies

infection in exquisite studies.<sup>31,58</sup> The process begins with movement of the virus through peripheral nerves to the central nervous system (CNS), CNS viral proliferation, and subsequent spread via peripheral nerves to many other tissues. The virus initially replicates in muscle cells, infecting the muscle spindle, then the nerve innervating the spindle, and subsequently moves centrally through the axons of these neurons. It appears in dorsal root ganglia within 72 hours of inoculation, prior to its appearance in spinal cord neurons. Other studies suggest that the neuromuscular junction may be another site of neuronal invasion.<sup>59</sup> A partial homology between rabies virus glycoprotein and several snake neurotoxins that bind specifically to the nicotinic acetylcholine receptor may explain this phenomenon.<sup>60</sup>

Natural rabies infection seems to require a period of local replication, possibly to increase the inoculum, before nervous system infection occurs. During this period, passive and active immunization can prevent spread of the virus into the nervous system and thus prevent the disease. Once the virus enters peripheral nerves, current therapies do not seem to prevent replication and spread. However, antibody delivery across the blood-brain barrier may allow more effective later treatments.<sup>61</sup>

Once the virus invades peripheral nerve cells, it moves via retrograde axoplasmic flow to their central processes,<sup>62,63</sup> in contrast to herpes simplex virus or tetanus toxin, which use microtubular transport.<sup>64</sup> Once in the spinal cord or brain stem, the virus spreads throughout the CNS, with virtually every neuron infected.<sup>24</sup> After CNS infection, the virus spreads to the rest of the body via the peripheral nerves. Direct viral replication occurs in the salivary glands, but the high concentration of virus in saliva also reflects shedding from sensory nerve endings in the oral mucosa.

The mechanisms by which rabies virus produces CNS dysfunction are obscure; in many cases pathologic evidence of neuronal necrosis is minimal. Interference with neurotransmission may be important,<sup>65,66</sup> and a nearly 30-fold increase in nitric oxide production suggests an excitotoxic mechanism.<sup>67</sup>

### IMMUNE RESPONSE

The human response to natural rabies infection is insufficient to prevent disease. This may be a consequence of an insufficient antigenic load,<sup>42</sup> but this contention is disputed.<sup>49</sup> Viral replication at an immunologically “privileged” site (the CNS) may also limit the host response. Rabies virus can produce immunosuppression<sup>68</sup>; only a few unvaccinated rabies patients develop measurable antibody.<sup>69</sup> Interleukin-1 production in the CNS during infection may explain the immunosuppressive effect.<sup>70</sup> Those who develop a cellular immune response to the virus tend to have the encephalitic form rather than the paralytic form, and they die sooner than those who do not mount such a response.<sup>71</sup>

Rabies virus may be able to persist in macrophages and may later emerge to produce disease.<sup>72</sup> This may explain the occasional cases with very long incubation periods.

### DIAGNOSIS

The diagnosis poses little difficulty in a nonimmune patient with hydrophobia after a bite by a rabid animal, but the presentation of rabies in places where domestic animals are

immunized is seldom this straightforward. As the disease becomes less common, physicians are less apt to consider the diagnosis. In some countries, an increasingly large percentage of cases are not associated with a known exposure to a potentially rabid animal (virologic studies frequently indicate that these cases are due to bat rabies viruses).

No diagnostic studies in the patient are useful during the incubation period; exposure to a potentially rabid animal should prompt prophylactic treatment rather than laboratory testing. Once symptoms begin, standard testing does not help distinguish rabies reliably from other encephalitides. The CSF is normal in the majority of patients but may reveal a lymphocytic pleocytosis (5 to 30 cells per microliter), normal glucose, and modest protein elevation (less than 100 mg/dL).<sup>73</sup> Imaging studies are not specific, except to exclude other potential causes such as herpes simplex encephalitis. Magnetic resonance imaging may show lesions involving basal structures of the brain.<sup>74,75</sup>

The most important early diagnostic test in symptomatic patients is immunofluorescent staining of a skin biopsy obtained from the nape of the neck, above the hairline because the virus localizes in hair follicles.<sup>76</sup> Approximately 50% of samples reveal rabies virus in the first week of symptoms, and this percentage increases thereafter.<sup>77</sup> This test is being supplanted by reverse-transcriptase polymerase chain reaction (rt-PCR) analysis of saliva for viral RNA (see <http://www.cdc.gov/ncidod/dvrd/rabies/Diagnosis/diagnosis.htm>).<sup>78</sup> The corneal impression test for infected cells is no longer commonly used.

The rapid fluorescent focus inhibition test (RFFIT) is the most commonly employed serologic test for neutralizing antibody.<sup>79</sup> In those receiving neither PET nor immunologic therapies, serum antibody is detectable in a small number of patients by day 6 of illness, in 50% by day 8, and usually in 100% by day 15. Any CSF levels are diagnostically valuable, including those of patients who received PET. CSF may also reveal the presence of specific oligoclonal antibodies not found in the serum as a method of confirming CNS infection.<sup>80</sup>

The reverse-transcriptase polymerase chain reaction (RT-PCR) is emerging as the diagnostic procedure of choice in suspected rabies.<sup>81</sup> This test can be performed on CSF, saliva, or tissues of patients. RT-PCR allows more specific determination of the geographic and host species origin of a particular rabies virus.<sup>82,83</sup> It can be successfully performed on decomposed brain material,<sup>84</sup> a situation in which older techniques failed.<sup>85</sup>

## Differential Diagnosis

The major differential diagnosis of furious rabies is that of another encephalitis. Lacking a known exposure to a rabid animal, and in those cases in which hydrophobia and hyperactivity are not prominent, it is difficult to distinguish between these possibilities.<sup>86</sup> Since rabies occasionally mimics herpes simplex encephalitis, some patients receive empirical therapy with acyclovir pending a more secure diagnosis. While no data are available concerning this approach, anecdotes regarding the use of vidarabine in rabies do not suggest that it alters the course of the disease.<sup>73</sup>

Tetanus may be confused with rabies, since opisthotonic posturing occurs in both.<sup>64</sup> However, the other findings in

rabies (e.g., hydrophobia) are not seen in tetanus, and the CSF is normal in tetanus. The spasms of rabies lack the marked stimulus sensitivity of tetanus, and patients with rabies lack the persistent rigidity of tetanus patients. Strychnine poisoning should be considered.

The paralytic form may variously resemble acute inflammatory polyneuropathy, transverse myelitis, or poliomyelitis. Electromyographic studies may distinguish rabies from polyneuropathy. The complaint of aching pain at the level of the lesion suggests transverse myelitis, as does a high T2 signal lesion in the spinal cord on magnetic resonance imaging. Sensory function is typically normal in rabies patients,<sup>49</sup> whereas a sensory level abnormality is characteristic of transverse myelitis. A high fever typically precedes the weakness of poliomyelitis, and the resolution of fever with the onset of neurologic findings may be a useful clue favoring this diagnosis over rabies. A history of poliomyelitis or immunization against it should be sought.

CNS reactions to the rabies vaccines available in more developed countries are exceptionally rare, but patients receiving older vaccine forms containing myelin determinants can develop acute disseminated encephalomyelitis (ADEM; also called postvaccinal encephalomyelitis; see Prevention). ADEM has many other known precipitants and may also be cryptogenic. ADEM may seem like a typical encephalitis or may present as a mass lesion resembling a brain abscess. It typically begins 10 to 14 days after vaccine exposure, an unusually brief incubation for rabies. In the absence of viral isolation, a high RFFIT titer in spinal fluid is evidence of rabies rather than of ADEM, even in patients who have been immunized.<sup>87</sup>

Some persons exposed to a potentially rabid animal may suffer a psychological reaction termed *rabies hysteria*.<sup>88</sup> They may refuse to attempt to drink, in contrast to those with rabies whose attempts to drink are halted by pharyngeal spasms.

## TREATMENT AND PROGNOSIS

There is no established treatment for rabies once symptoms have begun; almost all patients succumb to the disease or its complications within a few weeks of onset. Three survivors have been reported, two of whom apparently made full recoveries.<sup>39,43</sup> Each had undergone some form of PET, which probably modified their courses. Partial recovery occurred in another who received rabies vaccine without immunoglobulin.<sup>80</sup> A working group recently published suggestions for the treatment of rabies victims.<sup>89</sup> Using some of these recommendations, a single case of survival without postexposure treatment has been discussed in the press.<sup>90</sup>

Supportive therapy includes intubation, sedation, mechanical ventilation, fluid and electrolyte management, nutrition, and management of intercurrent illnesses and complications.<sup>45</sup> However, none of the patients reported has survived more than 17 days despite aggressive antirabies treatment and symptomatic care.

## PREVENTION

Rabies vaccination for prevention and PET was introduced in the nineteenth century, first by Galtier and later by Pasteur.<sup>91</sup>

While the control of animal rabies is central to the prevention of human disease, only a few nations have succeeded in eliminating rabies, and these maintain quarantine procedures lest the disease reappear. Thus, prophylaxis (for domestic animals and selected humans) and PET remain essential to the prevention of clinical rabies. Cat and dog rabies prophylaxis is mandated by law in many countries; for example, in the United States, 1- or 3-year vaccines are permitted (although only 3-year vaccines are recommended by the National Association of State Public Health Veterinarians).<sup>92</sup> Vaccination should be supervised by a veterinarian; improper administration can lead to lack of immunity.<sup>93</sup> Some vaccines lack potency; in developing countries, measuring animal seroconversion rates may be considered to ensure protection.<sup>94</sup> Immunizing livestock is recommended in areas of increasing prevalence.

Wild animal vaccination can be an effective veterinary public health measure. Vaccines that are effective after ingestion allow vaccination of free-ranging animals.<sup>95</sup> An intensive 4-year campaign in Belgium nearly eliminated rabies from the fox population. Veterinary vaccines prepared in continuous cell lines cost about \$0.50 per dose in the United States, in contrast to the Semple-type human vaccines costing about \$5 for a course; Vero cell vaccine in France costs about \$160 per course, and human diploid cell rabies vaccine (HDCV) in the United States costs more than \$500 per course.<sup>96</sup>

### Pre-exposure Prophylaxis

Pre-exposure prophylaxis is indicated for those with a relatively high risk of rabies exposure. This includes veterinarians, workers in laboratories using the virus, spelunkers, and those planning to visit countries with a high prevalence of dog rabies for more than 30 days. Recommendations for international travelers are available at <http://www.cdc.gov/>

diseases/rabies.html. A series of three intramuscular (or intradermal, if using a vaccine prepared for this route) injections over a 3-week course are sufficient; antibody response determination is not required in normal hosts. Booster doses are recommended every 2 to 3 years for persons remaining at risk of exposure. If antibody titers are checked, an adequate response is generally considered to be complete neutralization at the 1:5 level by RFFIT, which is equivalent to the 0.5-IU/mL concentration suggested by WHO.

### Postexposure Treatment

After exposure, rabies prevention begins with good wound care, which reduces the risk of rabies by up to 90%.<sup>97</sup> Wash the wound thoroughly with a 20% soap solution; this is as effective as the previously recommended quaternary ammonium compounds.<sup>98</sup> This should be followed by application of 70% ethanol or an iodine-containing solution. Wounds should not be sutured prior to a decision about PET; if a wound must be sutured, rabies immunoglobulin should be instilled into the wound and infiltrated around it (see later discussion). Failure to infiltrate wounds with rabies immunoglobulin, or surgical closure of wounds prior to immunoglobulin infiltration, have been associated with the development of rabies in patients despite otherwise proper PET.<sup>99</sup>

Following wound care, the clinician must decide whether to institute passive or active immunization. Prompt consultation with public health officials is advised, since this decision is based on the current incidence of rabies in the animal species involved in the exposure.<sup>100</sup> WHO recently summarized their recommended approach (Table 75-5).<sup>101</sup> The most recent report of the Immunization Practices Advisory Committee is also an important source of information.<sup>102</sup> A decision analysis model may be useful in deciding who should receive prophylaxis.<sup>103</sup>

**Table 75-5** World Health Organization Guide to Postexposure Prophylaxis

Category	Type of Contact with a Suspect or Confirmed Rabid Domestic or Wild* Animal, or Animal Unavailable for Observation	Recommended Treatment
I	Touching or feeding of animals; licks on intact skin	None, if reliable case history is available
II	Nibbling of uncovered skin; minor scratches or abrasions without bleeding; licks on broken skin	Administer vaccine immediately <sup>†</sup> ; stop treatment if animal remains healthy throughout an observation period <sup>‡</sup> of 10 days or if animal is euthanized and found to be negative for rabies by appropriate laboratory techniques
III	Single or multiple transdermal bites or scratches; contamination of mucous membrane with saliva (i.e., licks)	Administer rabies immune globulin and vaccine immediately <sup>†</sup> ; stop treatment if animal remains healthy throughout an observation period <sup>‡</sup> of 10 days or if animal is killed humanely and found to be negative for rabies by appropriate laboratory techniques

\*Exposure to rodents, rabbits, and hares seldom, if ever, requires specific antirabies treatment.

<sup>†</sup>If an apparently healthy dog or cat in or from a low-risk area is placed under observation, it may be justifiable to delay specific treatment.

<sup>‡</sup>This observation period applies only to dogs and cats. Except in the case of threatened or endangered species, other domestic and wild animals suspected as rabid should be euthanized and their tissues examined using appropriate laboratory techniques.

From World Health Organization, Emerging and Other Communicable Disease Branch: WHO Recommendations on Rabies Post-Exposure Treatment and the Correct Technique on Intradermal Immunization Against Rabies. Geneva, World Health Organization. Available at <http://www.who.ch/programmes/emc/vph.htm>.

In general, a healthy dog or cat in countries of low prevalence who has transferred saliva to a human is observed for 10 days. If the animal's behavior remains normal, the patient need not receive PET beyond proper wound care. If its behavior changes, it should undergo immediate pathologic examination for evidence of rabies infection; there is still adequate time to institute PET if rabies is confirmed. Wild mammal exposure, especially if the animal exhibits uncharacteristic behavior, warrants PET in most circumstances. If the animal is available for pathologic examination, and direct fluorescent antibody testing of the brain does not indicate the presence of rabies virus, PET may be discontinued. PET appears safe in pregnant women and should not be withheld for this reason.<sup>104</sup>

Antirabies immunoglobulin is available in both human (HRIG) and equine forms (pooled antirabies serum [ARS], and purified antirabies serum of equine origin [equine rabies immunoglobulin, ERIG]). These immunoglobulins are purified from donors hyperimmunized with rabies vaccine. The need for immunoglobulin administration with currently available vaccines is uncertain, but the consequence of vaccine failure indicates its routine employment. HRIG is given in a dose of 20 IU/kg, with half injected in the vicinity of the wound (see earlier discussion), and the remainder injected intramuscularly in the gluteal region. The dose of ERIG is 40 IU/kg.

Many different rabies vaccines have been produced since 1882. In some developing countries, vaccine prepared from virus grown in adult animal nerve tissue (Semple vaccine) is still employed, but it carries a risk of central and peripheral neurologic complications in the range of 1 in 200 to 1 in 1600 vaccinees.<sup>43</sup> Its efficacy is uncertain. Production of vaccine in sheep CNS, a common method of Semple-type vaccine production, also carries the theoretical risk of transmitting the scrapie prion.<sup>105</sup> Although these reactions are often assumed to be a consequence of an immune reaction to myelin basic protein in the vaccine, only a minority of patients appear to develop antibody against this constituent of myelin.<sup>106</sup> Suckling mouse brain vaccine is effective and safer, with a neurologic complication rate approximating 1 in 8000.

The currently employed human vaccines in the United States include HDCV and a vaccine grown in rhesus monkey diploid cell cultures (rabies vaccine, adsorbed, RVA). These vaccines are remarkably safe and immunogenic. Local reactions (pain, swelling, or induration) may be common, but systemic complaints (fever, headache, malaise, nausea, abdominal pain, or adenopathy) occur in a minority of patients. Serious reactions have been exceedingly rare, with Guillain-Barré syndrome reported in a few patients<sup>107</sup> and a chimpanzee.<sup>108</sup> Corticosteroids should not be given to patients experiencing a vaccine reaction unless that reaction is life-threatening because they interfere with the development of immunity. Immunocompromised patients may not respond adequately to vaccination and should undergo measurement of antibody titers 2 to 4 weeks after immunization to ensure adequate immunization.<sup>102</sup>

In other countries, other PET vaccines and regimens are often employed. Consultation with the rabies officer of the state health department may be helpful in the management of patients in whom PET has been initiated with a vaccine not approved for use in the United States.

The usual dose of HDCV or RVA for PET is 1.0 mL intramuscularly on the day of exposure (or as soon as possible

thereafter), repeated on days 3, 7, 14, and 28. If possible, the vaccine should be administered in the deltoid muscle. Gluteal injections, which may miss the muscle, have been associated with some vaccine failures. In small children, it may be given in the lateral thigh. The vaccine must not be given in the same region as the immunoglobulin. The intradermal vaccine was previously indicated only for pre-exposure prophylaxis, but current WHO recommendations include schedules for its use in PET (Fig. 75-4). Patients who have been previously vaccinated receive 1.0 mL on days 0 and 3 only, without rabies immunoglobulin.

A single case of a transient false-positive enzyme-linked immunosorbent assay for human immunodeficiency virus after HDCV immunization was reported in 1994.<sup>109</sup> Subsequent screening of samples from 50 patients recently immunized against rabies revealed no similar cases,<sup>110</sup> but in view of a similar phenomenon with other vaccines, physicians administering rabies vaccines should be aware of this possibility.

The limited extent of cross-protection among different lyssaviruses, and the possibility that antigenic differences in lyssaviruses from different locales may impair vaccine efficacy, should prompt future efforts to produce a vaccine effective against all *Lyssavirus* variants. The nucleic acid vaccine approach is promising.<sup>111</sup> Further research in these areas may

#### Standard WHO intramuscular regimen

Dose: one IM dose (1.0 or 0.5 mL) into deltoid

#### Reduced multisite intramuscular regimen (2-1-1)

Dose: one IM dose (1.0 or 0.5 mL) into deltoid

#### 8-site intradermal regimen (8-0-4-0-1-1)

Dose: 0.1 mL ID per site

#### 2-site intradermal regimen (2-2-2-0-1-1)

Dose: one ID dose = one fifth of IM dose (0.1 or 0.2 mL), ID per site

**FIGURE 75-4** World Health Organization recommendations for vaccine schedules.

produce a stable, inexpensive vaccine that could lead to simple, safe, and effective prophylaxis and PET.

Personnel caring for rabies patients should practice standard universal and respiratory precautions. In addition, they should receive a pre-exposure immunization sequence (see earlier discussion) and maintain a serum antirabies antibody titer of 0.5 IU/mL.<sup>112</sup> Exposures to potentially contaminated secretions or tissues should lead to standard PET.

# Human Retroviral Infections in the Tropics

STEVEN J. REYNOLDS  
PASCAL O. BESSONG  
THOMAS C. QUINN

## INTRODUCTION

Shortly after the recognition of the acquired immunodeficiency syndrome (AIDS) in homosexual men in North America in the early 1980s, similar cases of immunodeficiency were identified in heterosexual men and women in tropical areas such as the Caribbean and sub-Saharan Africa.<sup>1-6</sup> Subsequent epidemiologic and virologic investigations demonstrated that the human immunodeficiency virus (HIV) was the etiologic agent of AIDS and that HIV was widely prevalent in both the developing and developed world.<sup>7,8</sup> During these early years it became clear that AIDS, which was originally believed to be restricted to a highly selected population of homosexual men in the United States, was in fact a global pandemic, spreading relentlessly to all countries of the world and becoming one of the leading causes of mortality in young adults.<sup>9</sup> In the first decade of the epidemic, 10 million people became infected with HIV, and now more than 20 million people have died of AIDS and 40 million people are living with HIV.<sup>10,11</sup>

The pandemic comprises distinct epidemics among different populations and is now disproportionately affecting the developing world. Although the incidence of HIV has apparently leveled off in much of the developed world, it nevertheless continues to increase dramatically in populations of the Caribbean, Latin America, sub-Saharan Africa, Asia, and Eastern and Central Europe.<sup>11</sup> Despite having only 10% of the world's population, sub-Saharan Africa contains almost two thirds of all people living with HIV.<sup>11</sup> Because of the overwhelming immunosuppression associated with HIV infections, it is also anticipated that many endemic bacterial and parasitic diseases in these regions will increase dramatically. Diseases such as tuberculosis, toxoplasmosis, cryptosporidiosis, isosporiasis, and fungal infections, including cryptococcosis and *Penicillium marneffei*, will become more prevalent and result in increasing morbidity and mortality (see Chapter 133).<sup>12,13</sup>

## F. RETROVIRAL INFECTIONS

This chapter addresses the basic biology of human retroviruses, including HIV infection, the magnitude of HIV infections throughout the world, and the subsequent global response, with particular emphasis on the developing countries of the tropics. Chapter 133 further discusses the clinical presentation of HIV infection in people living in the tropics.

### AGENT

#### History

The beginning of the AIDS epidemic is often marked as 1981, when the cases of five young homosexual men with puzzling manifestations of immunodeficiency were reported from the city of Los Angeles. Because the epidemic was first recognized among homosexual men, the acronym GRID ("gay-related immune deficiency") was initially proposed. However, when it became apparent that the disease was also affecting intravenous (IV) drug users and blood transfusion recipients, the term AIDS was adopted. It is remarkable that heterosexual intercourse, now by far the most common mode of transmission worldwide, was not widely recognized as a risk factor for AIDS until several years later.

After an intensive hunt for an etiologic microbe, the lentivirus HIV-1 was shown to be the causative agent of AIDS in 1983–1984. The virus was originally called LAV for lymphadenopathy virus in France and HTLV-III for human T-cell lymphotropic virus type 3 in the United States. Subsequently, the International Committee for the Taxonomy of Viruses recommended the current designation, HIV.<sup>14,15</sup> Serologic tests for antibodies to HIV became widely available in 1985. Only then, after serosurveys were conducted in at-risk populations around the globe, was the staggering impact of the pandemic in tropical regions appreciated.

It is now clear that HIV infections were present among humans in equatorial Africa long before the clinical AIDS epidemic was first recognized. There are sporadic case reports of Europeans, such as physician-missionaries who provided medical care in sub-Saharan African countries, who developed mysterious AIDS-like conditions after their return home. In some cases stored specimens were recently tested to establish a diagnosis of HIV infection. One case was that of a young Norwegian sailor who had traveled extensively, including to "African ports," before he first became ill in 1966.<sup>16</sup> By 1976 he had apparently transmitted HIV and AIDS to his wife and their newborn daughter. Serum specimens from all three family members were HIV-1-positive. Another confirmed case is that of a Portuguese man who lived in Guinea-Bissau between 1956 and 1966 and who developed AIDS in 1974.<sup>17</sup> Serologic tests on multiple stored specimens showed that he was HIV-2-infected. In these cases there was a travel history compatible with having become infected in Africa, clinical disease compatible with AIDS, and good enzyme-linked immunosorbent assay (ELISA) and Western blot serologic evidence of HIV infection. However, such reports of rare early HIV/AIDS cases must be interpreted cautiously, for in other touted early cases of HIV in travelers the diagnosis was proved to be erroneous.

Retrospective serologic studies on stored serum samples have also identified early (pre-1981) cases of autochthonous transmission of HIV in sub-Saharan Africa. One positive specimen was a plasma sample that had originally been obtained as part of immunogenetic studies from a donor in Leopoldville (now Kinshasa, Democratic Republic of Congo) in 1959.<sup>18</sup> When thawed and tested 27 years later, the sample was strongly positive by ELISA, immunofluorescence, Western blot, and immunoprecipitation for HIV-1 antibodies, and tests were negative in appropriate control assays. Even more solid evidence for early prevalence of HIV in Africa was obtained by a retrospective study of serum specimens that had coincidentally been collected in 1976 from apparently healthy persons in northern Zaire (now Congo) as part of a survey for Ebola virus antibodies. When these frozen serum specimens were thawed and tested a decade later, five were found to be antibody-positive for HIV. Three of these patients were then relocated, and all were again confirmed to be HIV-seropositive. HIV-1, genotype A (the Z321 strain), was obtained by blood culture from one of these patients.<sup>19–21</sup>

Collectively these studies show that HIV viruses—strains not dissimilar from contemporary HIV strains—were present, probably at low levels, in equatorial Africa in the 1950s, 1960s, and early 1970s. However, it was not until the late 1970s and early 1980s that the AIDS epidemic became clinically apparent in Africa. Because there were no rare and unique “marker” opportunistic infections in Africa—a role served by *Pneumocystis carinii* infections in Los Angeles—it is more difficult to date the onset of the African AIDS epidemic. Only by reconstructing epidemic curves for certain readily diagnosed but less common infections, such as cryptococcal meningitis (in Kinshasa) or herpes zoster (in Lusaka, Zambia), was it possible to roughly bracket the onset of the African AIDS epidemic. We now know that by the time the AIDS epidemic was first recognized, it had been preceded for several years by a silent HIV epidemic.

By the end of 1984, a global pattern had emerged in which most AIDS cases among Africans and Haitians, whether they lived in their home countries or abroad, were associated with heterosexual intercourse, whereas most cases among North Americans, Europeans, and South Americans (largely Brazilians) were associated with homosexual sex or IV drug use. Early reports of a relatively high AIDS incidence regrettably led to irrational discrimination against Haitians in the United States.

### Taxonomy of HIV and Other Lentiviruses

HIV, like all other retroviruses, is an enveloped, positive-stranded RNA virus. Particles are approximately 110 nm in diameter and contain a cone-shaped core of nucleoprotein. The virus is “diploid” in that the genome consists of two essentially identical dimerized full-length strands of approximately 10,000 ribonucleotides. Viral particles also contain reverse transcriptase, the enzyme that copies the RNA into double-stranded DNA (complementary plus- and minus-strands) that becomes integrated into the host cell genome as a provirus. Genome sequencing has clarified the phylogenetic relationships between the lentiviruses of nonprimate mammals, of nonhuman primates, and of humans.<sup>22</sup>

Lentiviruses (Latin *lentus*, “slow”) are retroviruses that are known to naturally infect only large and long-lived mammals,

including ungulates, felines, and primates. The lentiviruses can produce a variety of disease syndromes in their natural hosts: The feline immunodeficiency virus (FIV) causes an AIDS-like illness in wild and domestic cats<sup>23</sup>; the bovine immunodeficiency-like virus (BIV) is not clearly pathogenic for any bovines<sup>24</sup>; the visna-maedi virus (VMV) causes pneumonia and encephalitis in sheep; the caprine arthritis encephalitis virus (CAEV) causes arthritis and encephalitis in goats<sup>25</sup>; and the equine infectious anemia virus (EIAV) causes a recurrent febrile illness with anemia in horses.<sup>26</sup> Natural modes of transmission are not completely understood for most animal lentiviruses. EIAV has been clearly shown to be mechanically transmissible from horse to horse by horsefly (tabanid) bites.<sup>27</sup>

Distinct lentiviruses have been detected in five nonhuman primate species. These include sooty mangabeys (SIV<sub>SMM</sub>), Sykes' monkeys (SIV<sub>SYK</sub>), African green monkeys (SIV<sub>AGM</sub>), mandrills (SIV<sub>MND</sub>), and chimpanzees (SIV<sub>CPZ</sub>).<sup>28</sup> Measured prevalence of SIV in wild populations of monkeys have in some cases exceeded 30%. All of these are Old World species native to sub-Saharan Africa. No primate lentiviruses have been found in wild populations of primates outside of Africa. The lentivirus that infects sabaeus monkeys (SIV<sub>SAB</sub>) in nature has been clearly shown to have arisen as a recombination between SIV<sub>AGM</sub> and SIV<sub>SMM</sub>.<sup>29</sup>

The first reports of nonhuman primate lentiviruses were of isolates from colony-held Asian rhesus macaques in the United States.<sup>30,31</sup> This virus was originally named simian T-cell lymphotropic virus type III (STLV-III), then SIV<sub>MAC</sub>. However, no SIVs have been detected in any Asian macaque species in the wild. Given the close phylogenetic relationship of SIV<sub>MAC</sub> with SIV<sub>SMM</sub>, it is now widely accepted that SIV<sub>MAC</sub> is simply an SIV<sub>SMM</sub> strain that was accidentally transmitted from sooty mangabeys to rhesus macaques in captivity. Similarly, SIV strains isolated from colony-held nemestrina macaques (SIV<sub>MNE</sub>) and stump-tailed macaques (SIV<sub>STM</sub>) in the United States are also thought to have originated through accidental transmissions of SIV<sub>SMM</sub> to these species in captivity, either through cohousing or intentional cross-species inoculations of tissues in biomedical research.

There are two major lentiviruses of humans—HIV-1 and HIV-2—in addition to two groups of less well defined assortments of viruses loosely related to HIV-1, informally referred to as HIV-1-O [outlier] group and HIV-1-N [non-M, non-N].<sup>32–35</sup> HIV-1 and HIV-1 outlier strains also roughly cluster with the SIV<sub>CPZ</sub> branch of primate lentiviruses, while HIV-2 strains cluster tightly with the SIV<sub>SMM</sub> branch. These phylogenetic relationships of humans with simian lentiviruses have obvious implications regarding the origin of human HIV and AIDS.<sup>36</sup>

Thus far, HIV-1-O group viruses have been found only in persons from Cameroon, Gabon, or Equatorial Guinea. The designation “HIV-1-M [main] group” has informally been used to distinguish the globally predominant HIV-1 genotypes from viruses in the geographically restricted and incompletely characterized HIV-1-O and HIV-1-N. Nucleotide sequences have been determined for thousands of HIV strains from around the world, and these have been placed into phylogenetic clusters. Different research groups have sequenced and analyzed different regions of the viral genome.<sup>37,38</sup> With a few important exceptions, the phylogenetic relationships based on different regions of the genome, such as *gag* or *env*, are closely congruent. Within each of the HIV types (HIV-1 and HIV-2) there are a number of discrete genotypes or clades.

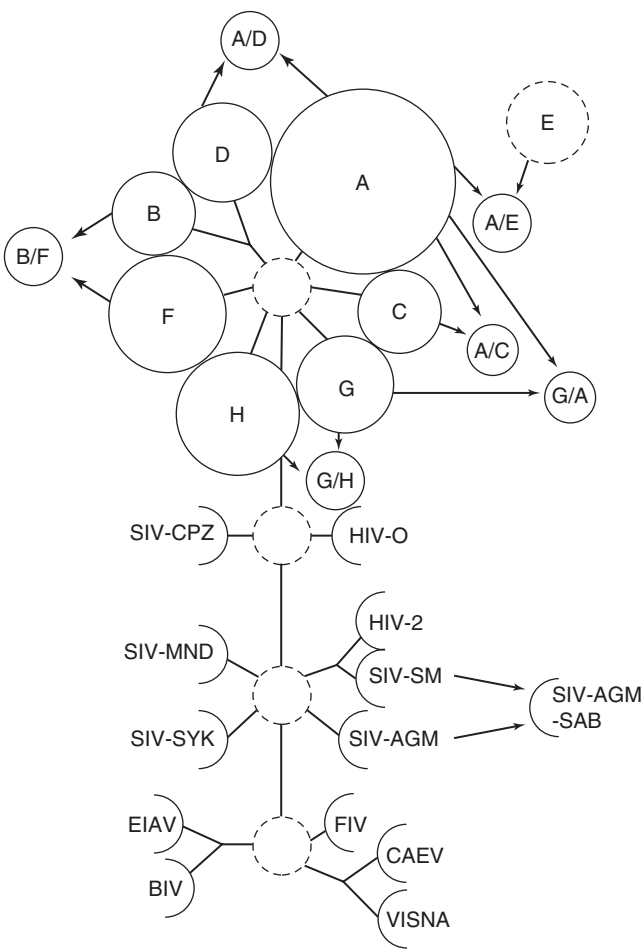

By convention these are given letter designations, in an order that roughly reflects the order of their discovery. Nine genotypes of HIV-1 group M have been identified, termed HIV-1 A–D, F–H, J, and K. This classification uses phylogenetic and distance analyses of at least three regions of the genome.<sup>39,40</sup> All clades are roughly equidistant from each other in a “star” phylogeny; no virus or clade is an obvious candidate as the progenitor virus for other clades. Maximum *env* gene differences between HIV-1 strains within a clade are no more than 15%, whereas differences between strains of different clades may be as great as 20% or 30%. The oldest known HIV-1 isolate, Z321 virus from the then Zaire in 1976, is an HIV-1 A clade virus. Five genotypes of HIV-2 have been identified, HIV-2A through E. As with HIV-1, no HIV-2 virus or clade is a clear progenitor.<sup>41</sup>

The taxonomy of primate lentiviruses has been complicated by the finding that many strains appear to be naturally occurring recombinants. A variant formerly designated as subtype E based on the *env* gene sequence was later shown to be a recombinant between clades A and E,<sup>42</sup> though a nonrecombinant clade E (pure clade E), has not been found. Interclade A/E possesses *gag* and *pol* genes, which are homologous to clade A viruses, but the *env* gene comes from an as yet undetected clade E. Consequently, clade E is not recognized as a separate cluster of closely related viruses. In a similar vein, previously tagged clade I based on the C3V3 sequence<sup>43</sup> has been shown to be a complex recombinant comprising clades A, G, and regions that do not fall within any presently known defined clade.<sup>44,45</sup> These interclade recombinants have been termed circulating recombinant forms (CRFs), since they contribute significantly to the global epidemic. As a result, previously known subtypes E and I are now referred to as CRF01\_AE and CRF04\_cpx, respectively. Other CRFs include CRF02\_AG, which represents a recombination between clades A and G and circulates in West and Central Africa,<sup>46,47</sup> and CRF03\_AB, which represents a clade A/B recombinant form has mostly been responsible for the epidemic among IV drug users in Kalinigrad.<sup>48</sup> Currently described CRFs found in the literature are presented in Table 76-1 and Fig. 76-1.

**Table 76-1** Identified Circulating Recombinant Forms and Their Subtype Components

CRF	Clade Components
CRF01_AE	A, E
CRF02_AG	A, G
CRF03_AB	A, B
CRF04_cpx	A, G, H, K, U
CRF05_DF	D, F
CRF06_cpx	A, G, J, K
CRF07_BC	B', C
CRF08_BC	B', C
CRF09_cpx	A, F, G, U
CRF10_CD	C, D
CRF11_cpx	A, CRF01_AE, G, J
CRF12_BF	B, F
CRF13_cpx	A, CRF01_AE, G, J, U
CRF14_BG	B, G
CRF15_01B	CRF01_AE, B
CRF16_A2D	A2, D

U, unclassified sequence.

**FIGURE 76-1** Schematic diagram of the lentivirus phylogenetic tree showing the known lentiviruses of nonprimate mammals (BIV, bovine immunodeficiency virus; CAEV, caprine arthritis and encephalitis virus; EIAV, equine infectious anemia virus; FIV, feline immunodeficiency virus), of nonhuman primates (AGM, African green monkey; CPZ, chimpanzee; MND, mandril; SAB, sabaeus monkey; SIV, simian immunodeficiency virus; SM, sooty mangabey; SYK, Sykes’ monkey), and the human viruses (HIV, human immunodeficiency virus types 1 and 2 and type 1 “outlier” strains, which are shown at HIV-O). For the human HIV viruses, the clades are shown as circles with the size of the circles roughly proportional to the known genetic diversity of the viruses within each clade. Recombinant strains are shown as the convergence points of arrows from defined clades. The parent E clade virus that contributed genes to the widely prevalent E/A recombinant clade is only hypothetical and therefore shown as a dashed circle.

### Host Range and Cross-Species Infections

Laboratory studies with the primate lentiviruses suggest that cross-species infections can and do occur. Essentially all SIVs can grow in vitro in cultures of human lymphocytes. Several research workers and animal handlers have become infected with SIV strains through laboratory accidents. At least one human has developed a chronic infection with SIV<sub>SMM</sub>. Human HIV-1 strains readily infect chimpanzee lymphocytes in vitro and live chimpanzees in vivo, but HIV-1 strains infect other primate species weakly or not at all.<sup>49–51</sup> Chimeric “SHIV” strains, SIV/HIV-1 recombinant viruses genetically engineered in research laboratories for use in vaccine studies, show

intermediate growth properties.<sup>52</sup> Low-passage human-derived HIV-2 strains infect a wide variety of nonhuman primate species with ease. Genetic studies of captive primates suggest that SIV<sub>SMM</sub> has on at least three occasions jumped to a new species within a primate colony.

Remarkably, SIVs that can cause AIDS in heterologous hosts typically do not cause immunodeficiency in their native nonhuman primate hosts. For example, sooty mangabeys are unaffected by SIV<sub>SMM</sub>, but if this same virus is inoculated into rhesus macaques it causes AIDS. Similarly, African green monkeys appear to be totally unaffected by SIV<sub>AGM</sub>, but this virus in pigtailed macaques causes AIDS. These observations suggest that SIVs may have coevolved with their host species. There is no evidence that feline or ungulate lentiviruses can infect primates, although in vitro infection of human and primate cells by FIV has been reported.<sup>53</sup>

### Scientific Evidence on the Origin of HIV and AIDS

Several lines of evidence suggest that HIV-2 entered the human population directly from sooty mangabeys. Key observations are the following. SIV is a benign, highly prevalent virus in sooty mangabeys; SIV<sub>SMM</sub> grows well in human cells in vitro and can infect humans in vivo (laboratory workers); the natural habitat of sooty mangabeys in West Africa corresponds closely to the regions of highest human HIV-2 prevalence; and most important, HIV-2 is essentially genetically indistinguishable from SIV<sub>SMM</sub> (given a viral isolate with no additional information, it would be impossible to be certain whether it was obtained from a sooty mangabey or a human). Even more suggestive are recent molecular epidemiologic studies showing that HIV-2 strains from a given West African country are more similar to SIV<sub>SMM</sub> strains from that country than they are to other HIV-2 strains from other countries. These data suggest not only that SIV<sub>SMM</sub> emerged from sooty mangabeys into humans, but that it may even be “continuously emerging” through repeated cross-species transmissions. The exact mechanism of transmission remains uncertain. Mangabeys that are kept as pets may infect humans through bites or scratches, and hunters or food preparers may become infected through direct contact with blood when mangabeys are killed as a food source.

How HIV-1 may have originated in human populations is not so clear. Reasoning by analogy with HIV-2, one possibility is that HIV-1 simply represents a nonhuman primate virus that became “humanized” after a cross-species transmission. Data indicate that HIV-1 emergence resulted from three independent cross-species transmission events that gave rise to HIV-1 groups M, N, and O. All HIV-1 groups are closely related to SIV<sub>CPZ</sub>,<sup>54</sup> and recent sequence and phylogenetic analyses strongly tie the origin of HIV-1-N to SIV<sub>CPZ</sub>.<sup>34</sup> Again, additional sampling in this region might provide crucial information.

One clue to the origins of HIV-1 may be the remarkable genetic diversity of HIV-1, HIV-1-O, and HIV-1-N viruses among humans in the equatorial African countries that encompass the Congo River basin rain forest. Eight HIV-1 clades and at least three HIV-1-O clades can be found in this region, whereas in all other parts of the world no more than one or two clades are highly prevalent and autochthonously transmitted.

Furthermore, a high proportion (perhaps 25%) of the HIV-1 viruses in this geographic region are interclade recombinants.<sup>55</sup> The high level of diversity and frequent recombination suggest that HIV-1 and related viruses may have been prevalent in equatorial Africa for quite a long time. Instead of a simple recent direct emergence (as occurred for HIV-2), it appears more likely that the current epidemic HIV-1 strains emerged some time ago and have been continuously evolving in human populations. Successively more transmissible forms may have arisen and propagated among humans through natural selection. Careful molecular epidemiologic studies of HIV-1, HIV-1-O, HIV-1-N, SIV<sub>CPZ</sub>, and other primate lentiviruses in the African rain forest could shed considerable light on the emergence and evolution of HIV-1.

### Viral Genome Organization

Like all retroviruses, the life cycle of HIV is characterized by alternating stages in which the genetic information is carried by DNA or by RNA: the proviral (intranuclear) stage and the viral (extracellular) stage, respectively. Proviral DNA—viral genetic information that is integrated into the host cell genome in the form of DNA—is transcribed and translated, and full-length plus-strand RNA transcripts are packaged into virions, using conventional cellular machinery. Genetic information is routed back from free viral RNA to the host cell proviral DNA form by unique viral enzymes for reverse transcription and integration.

All retroviruses have in common three major genes: the *gag*, *pol*, and *env* genes.<sup>56</sup> The *gag* gene was so named because in early serologic studies cross-reactions were most readily detected with these antigens, hence “group-specific antigen,” or *gag*. The *pol* and *env* genes encode polymerase and envelope proteins, respectively. The large precursor proteins expressed from all three of these major genes are subsequently cleaved into smaller functional proteins. In HIV-1 the *gag* p55 precursor is cleaved into the p17 matrix protein and the p24 capsid, p7 nucleocapsid, and p6 proteins. The latter three proteins collectively form the viral core. The *pol* gene is translated as part of a *gag-pol* frameshift read-through polyprotein, which is cleaved into a p15 protease, a p66/p51 heterodimer with reverse transcriptase and RNAase H activity, and a p32 integrase. The *env* gene encodes a p90 protein that is heavily glycosylated to become gp 160, which is cleaved into surface gp 120 and a transmembrane gp41. Protein sizes and cleavages differ somewhat between human and primate lentiviruses, but overall the coding and expression patterns are similar (Fig. 76-2).

The genomes of HIV and related viruses contain genes that encode viral regulatory proteins—*tat* (transactivator of transcription) and *rev* (transport of structural protein messenger RNA [mRNA], especially *env*)—which are important in governing viral transcription and translation. In addition, HIV-1 has four open reading frames from which proteins are expressed in vitro and probably in vivo, commonly called the “accessory genes”: *vif* (viral infectivity factor), *vpr* (viral protein R), *vpu* (viral protein U), and *nef* (negative factor). *Vif* and *vpr* are particle-associated, whereas *vpu* and *nef* are not. These accessory genes are highly conserved in nature but are not essential to replication in vitro, and although much is

**FIGURE 76-2** Genome organization of HIV-1. Long terminal repeats (LTRs) are shown as broad rectangles at the 3'- and 5'-terminals of the genome. Open reading frames are shown as narrower rectangles with their designated gene names. See text for full names and functions of genes.

known about the biochemical properties of these gene products, their vital functions remain uncertain.

The suggestion has been made that the lentiviruses, along with the BLV and HTLV group of viruses (bovine leukemia and human T-cell lymphotropic virus) be classified as “complex retroviruses” because of their unique ability to regulate expression of their own genes through feedback loops.<sup>57</sup>

This self-regulating property may be important in the establishment of chronic infections in long-lived hosts.

**Viral Life Cycle**

The primate lentiviruses all share essentially the same replication cycle (Fig. 76-3).

**FIGURE 76-3** Schematic representation of the life cycle of HIV in a cell. The outer boundary is the cell membrane, and the inner boundary is the nuclear membrane. 1, free virus; 2, binding and entry; 3, reverse transcription; 4, nuclear transport; 5, integration; 6, transcription and splicing; 7, translation; 8, glycosylation; 9, membrane transport; 10, assembly and budding; 11, virion release and maturation.

## Attachment, Penetration, and Uncoating

When a free virion comes into contact with a cell surface, the first specific attachment is made between a specific region of the HIV gp120 surface envelop glycoprotein and the 58-kD cell-surface CD4 molecule.<sup>58</sup> The CD4 molecule is a member of the immunoglobulin superfamily that is expressed on the surface of T lymphocytes (and at lower levels on other cells) and normally serves as a corecognition factor for major histocompatibility complex (MHC) class II in antigen presentation. The gp120-CD4 interaction initiates conformational changes in gp120, which then permit interaction of gp120 with a second cell surface receptor, the CXCR4 chemokine receptor molecule (on T lymphocytes) or the similar CCR5 molecule on macrophages.<sup>59</sup> Fusion of the viral lipid bilayer membrane with the cell membrane is mediated by a specific hydrophobic region fusion domain of the viral gp41 transmembrane protein. Sequential binding of gp120 to CD4 and CXCR4 (or CCR5) is thought to trigger gp41 to “harpoon” the cell membrane lipid bilayer. The process then repeats with many virion gp120 molecules interacting with the cellular receptors until fusion is complete. Fusion can proceed at neutral pH typical of extracellular fluids.

## DNA Synthesis, Nuclear Transport, and Integration

Once the virus has inserted itself into the cytoplasm, the reverse transcriptase becomes activated and DNA proviral synthesis begins.<sup>60–62</sup> The initial event in reverse transcription—copying of virion RNA into DNA—is primed by cellular lysine transfer RNA (tRNA) (other retroviruses use other tRNA primers). The HIV reverse transcriptase molecule carries out three distinct enzymatic functions: (1) synthesis of a complete DNA negative strand using the virion RNA template, (2) degradation of the virion RNA template as the DNA strand is synthesized, and (3) synthesis of a DNA positive strand using the newly synthesized complete DNA negative strand. The net product is double-stranded DNA synthesized from an RNA template.

The sequences of the virion RNA and the proviral DNA are identical in their mid genome (protein coding regions) but differ in the arrangement of repeat and unique noncoding sequences at their terminals. In viral RNA, the order is repeat, 5′ unique, *gag-pol-env*, 3′ unique, repeat. As a consequence of a somewhat complicated series of head-to-tail jumps of the transcriptase that occur in synthesis of both the negative and positive DNA strands, this order becomes altered such that in the final double-stranded DNA provirus it becomes unique 3′, repeat, unique 5′, *gag-pol-env*, unique 3′, repeat, unique 5′. The U3-R-U5 sequence at both terminals is called the long terminal repeat, or LTR. When viral RNA is forward-transcribed, the outer unique regions of the proviral LTR DNA are not copied. This overall schema is thought to be necessary to provide for efficient priming and complete copying of both terminals. Occasionally aberrant reverse transcription occurs leading to covalently closed DNA circles containing either one or two LTRs, but these forms are dead-end.

In contrast to other retroviruses, HIV and the lentiviruses do not require that the newly infected cell undergo mitosis for integration to occur. The synthesized double-stranded DNA

copy of the viral sequences is transported to the nucleus as a preintegration complex (PIC) probably through microtubules. The nucleophilic behavior of PIC is thought to be influenced by import signals under the control of integrase, viral protein R (vpr), the DNA flap, and the p17 matrix protein.<sup>63–65</sup>

Integration is not site-specific in the host cell chromosome; apparently it can occur anywhere. However, chromosomal sites that are transcriptionally active are more likely, presumably because the chromatin structure is more open and accessible. Proviral integration is catalyzed by the viral integrase and involves 3′ end processing of both viral DNA strands, and strand transfer of both host cell DNA strands to the activated 3′ proviral ends.<sup>66,67</sup> Because the activated 3′ viral DNA strands invade the host cell DNA strands at sites a few nucleotides apart, there is a characteristic short duplication of host cell sequence flanking both ends of the newly integrated provirus.

## Gene Expression

The LTRs are organized such that the integrated provirus has a built-in 5′ promoter-enhancer and a 3′ polyadenylation site. The key activator on the HIV-1 5′ LTR promoter is the NF-κB binding site. Since NF-κB serves as an important cell activation factor, HIV transcription is unregulated concurrently with cell activation. The virus-encoded tat protein also increases viral transcription by binding to the tar RNA secondary structure in the 5′ LTR promoter region. An important consequence of this feedback loop is that HIV transcription is autocatalytic.<sup>68–70</sup> HIV transcripts are typically spliced into a large number of RNAs of different lengths. Spliced RNAs are efficiently transported from the nucleus and translated. However, long and unspliced RNAs (those containing the mid-env “rev responsive element,” or RRE) are not transported unless the early viral protein rev is present in abundance.<sup>71,72</sup> Transport is mediated by rev binding to the RNA secondary structure formed by the RRE sequence.

## Particle Assembly and Budding

Uncleaved gag precursor protein molecules and a much smaller number (5%) of gag-pol read-through proteins are targeted to the interior surface of the cell membrane by their myristoylated N-terminals. Viral core proteins are thereby aligned from outermost to innermost according to their position in the polyprotein: p17 matrix, p24 capsid, and nucleocapsid from the gag precursor, and then protease, reverse transcriptase, and integrase from the pol precursor. Cleavages are self-catalyzed by the viral encoded protease.<sup>73</sup> HIV protease is an aspartic protease which is active only as a dimer; virion assembly is thought to activate the protease. The nucleocapsid protein, the innermost of the gag proteins, interacts directly with a packaging site on full-length viral RNA via a complex of cystine residues (similar to a zinc finger motif in DNA binding proteins) and thereby guides genome encapsidation.<sup>74</sup> Independently, full-length gp160 envelope protein is oligomerized, glycosylated, and cleaved by cellular protease in the endoplasmic reticulum (ER) and Golgi apparatus into gp120 and gp41.<sup>75,76</sup> Envelope protein on the outer cell surface interacts with the p17 matrix (gag) protein via an internal cytoplasmic region of the gp41 transmembrane protein.

## Genetic Organization of Human Lentiviruses from Tropical Regions

The genetic structures of HIV-1, HIV-2, and HIV-O strains thus far studied are quite similar. The most obvious difference is that *p16 vpu* is found only in HIV-1, while *p16 vpx* is found only in HIV-2 (and primate SIV strains). These two genes (of uncertain function) are present in different locations in the mid-genomic accessory gene region. Among the HIV-1 strains the genomic structure is highly conserved despite substantial nucleotide sequence variation. Potentially significant variations between HIV-1 strains have been observed in the number of SP-1 and NF- $\kappa$ B binding sites in the LTR promoter regions, particularly among non-B clade viruses, but these have not been systematically studied. Few attempts have been made to compare the molecular biology of clades, and no clear differences have been found.

## Cell Tropism

Human and primate lentiviruses can infect a variety of cell types in vitro under relatively artificial laboratory conditions, but there is no convincing evidence that any cells except those of the mononuclear leukocyte lineages are infected in vivo. CD4<sup>+</sup> T lymphocytes were the first cells found to be infected (hence the originally proposed name HTLV-III), but a variety of macrophage-related cells (blood monocytes, skin Langerhans' cells, lymph node dendritic cells) also appear to be infected.<sup>77,78</sup> The presence of the two receptors—CD4 and CXCR4 (or CCR5)—appears to define the population of human cells that are permissive to HIV infection.

HIV-1 strains collected from blood early in infection are genetically homogeneous and uniformly display a characteristic “macrophage-tropic” envelope sequence.<sup>79,80</sup> As infection progresses over months and years, genetic variation in the blood increases so that the viral population becomes a quasispecies of genomes that may differ by 5% or more in their nucleotide sequences. Variation occurs in all genes, including the envelope, where mutations occur that change the affected virions from a macrophage-tropic to a “T cell-tropic syncytium-inducing” phenotype. The reason for this change in phenotype is not very clear, though it could be attributed to changes in the V-3 loop and V-2 region of the envelope protein, since these regions appear to determine coreceptor usage.<sup>81,82</sup> However, these altered viruses could as well be vertically transmitted.<sup>83</sup> The importance of CCR5 as a coreceptor is highlighted in the high degree of resistance to HIV-1 infection by certain individuals who show a 32-base-pair deletion in the CCR5 gene. The prevalence of this mutation is estimated to be about 16% in Caucasians, and 1% are homozygous for this trait.<sup>84</sup> Because most new infection initiates with a macrophage-tropic variant, these observations are consistent with a viral life cycle in which macrophage-tropic viruses are the person-to-person transmissible forms and T cell-tropic viruses are the immunologically destructive forms. This suggests a “queen-drone” relationship between the transmission-competent macrophage-tropic genomes and the host-confined T cell-tropic genomes. Based on the type of HIV-1 target cells, the cytopathic effect produced, and the coreceptor preferred, the majority of HIV-1 strains could be classified as three types of viruses: CCR5 viruses

(R5) that use CCR5 as coreceptor, infect macrophages, and do not cause syncytia; CXCR4 viruses (R4) that use CXCR4 as coreceptor, infect T cells, and cause syncytia, and CCR5/CXCR4 viruses (R5X4) that are dual tropic.<sup>85,86</sup> M-tropic viruses predominate at the onset of infection and throughout the asymptomatic and symptomatic phases. However, evidence suggests a switch from CCR5 usage to CXCR4 for certain viruses in some individuals in the late symptomatic phase of HIV-1 infection (AIDS). As a result, there is a pool of R5, X4, and R5X4 viruses.<sup>87,88</sup>

## Evolvability of Lentiviruses: Mutation and “Sexual” Recombination

HIV is highly evolvable through its combined properties of a high mutation rate and frequent recombination. Because HIV reverse transcriptase (like all RNA-dependent viral polymerases) lacks a proofreading and error-correcting mechanism, the nucleotide misincorporation rate is high, typically about 1 error per 10,000 nucleotides, or about one misincorporation per new genome. With its high replication rate, HIV rapidly generates a swarm of related sequences, essentially all of which differ from each other by varying degrees, from at least one nucleotide somewhere along the genome to as many as 500 nucleotides (5%). Most of these new mutations do not improve the genome fitness, and many are lethal. However, many mutations are near neutral in survival value and others may confer a slight advantage.

HIV, like all retroviruses, is “diploid,” in that each virion contains two complete, replication-competent RNA strands. No other viral families are diploid (some, like the reoviruses, are, of course, double-stranded; with complementary plus- and minus-strands). If a cell becomes coinfecting with two different HIV strains, progeny virions may be “heterozygous,” with one strand from each parent. Recombination occurs when such a heterozygous virion subsequently infects a new cell. Because the two strands are held in close proximity through a 5' RNA dimerization sequence, the reverse transcriptase can jump back and forth across strands giving rise to “copy choice” recombination. In some ways, this aspect of the viral life cycle is “sexual” in that parental genomic information is copackaged and recombined, with progeny showing genetic features of both parents. The observation that a high proportion of HIV-1 strains from equatorial Africa are recombinant between clades suggests that recombination occurs readily in vivo in infected humans. It seems likely that when new selective pressures are applied on HIV in vivo (such as antiviral drugs), recombination will be an important mechanism for evolution of maximally fit variants.<sup>89</sup>

## OTHER HUMAN RETROVIRUSES (INCLUDING HUMAN T-CELL LYMPHOTROPIC VIRUSES TYPES I AND II)

### Transposable Elements and Endogenous Retroviruses

The normal eukaryotic genome is studded with a large number of genetic elements that show similarity to retroviruses.<sup>90</sup> These “normal” mobile genomic regions, called transposons or

retrotransposons (depending on whether they encode a reverse transcriptase), can undergo limited replication and reinsertion within the genome but cannot be transmitted from one host cell to another. Other genomic elements show even closer homology to full retroviruses and are thought to represent defective remnants of retroviruses that became stably integrated into the genome in the recent evolutionary past. These endogenous retroviruses can rarely become activated, or they can recombine with other related retroviruses to yield replication-competent chimeric progeny retroviruses. Transposable elements and endogenous retroviruses are thought to be the cause of a number of genetic abnormalities, malignancies, and autoimmune diseases.<sup>91–93</sup>

### Primate Retroviruses

Some retrovirus genera have been found in primate species but not in humans.<sup>94</sup> These include the simian sarcoma virus; a mammalian C-type, oncogene-containing, replication-competent virus; and the Mason-Pfizer virus, a D-type replication-competent virus that can cause a fatal immunodeficiency disease in monkeys (simian AIDS, or SAIDS).<sup>95</sup> Human infections with these viruses have not been reported, but it is not known whether exposed humans are susceptible to infection. Other retrovirus genera are known to infect both nonhuman primates and humans, such as the human and simian foamy viruses. The foamy viruses, so named for their cytopathic effect on cells in culture, are also called spumaretroviruses.<sup>96</sup> They can exist as exogenous replication-competent viruses but apparently are benign.

### HTLV-I and HTLV-II

The first isolation of HTLV-I was reported in 1980 in a T-cell line from a patient with a T-cell leukemia/lymphoma. The viruses were found to be similar in morphology and genomic organization to the bovine leukemia virus, a retrovirus that causes B-cell lymphomas in cattle.<sup>97</sup> Shortly thereafter, another related virus, HTLV-II, was identified in a T-cell line from a patient with hairy cell leukemia. These and related viruses are now collectively classified as the HTLV-BLV group. HTLV-I and -II have an overall genomic structure typical of retroviruses, with LTRs and *gag*, *pol*, and *env* genes. The HTLV-BLV group viruses are similar to the lentiviruses in that they are complex retroviruses with specific viral-encoded mechanisms for transactivation and RNA transport; the *tax* and *rex* genes of HTLV-I and -II are analogs of the HIV *tat* and *rev* genes. HTLV-I and -II share about 65% similarity in their nucleotide sequences. Within HTLV-I, strains from different parts of the world are genetically much less diverse than are HIV-1 strains, showing only about 7% sequence divergence. Clade or subtype systems have been proposed for HTLV-I and for HTLV-II in a manner similar to HIV. It is often possible to reconstruct the epidemiologic spread of HTLV-I epidemics using genetic sequence data.<sup>98</sup>

HTLV-I is proved to be causally associated with adult T-cell leukemia (ATL) and neurologic diseases of spinal cord known in the Caribbean as tropical spastic paraparesis (TSP) and in Japan as HTLV-associated myelopathy (HAM).<sup>99,100</sup> There have been clinical reports of HTLV-I and -II associated with chronic arthropathy and with uveitis, but a causal relationship remains unproved. HTLV-I can present at a variety of stages: asymptomatic, with

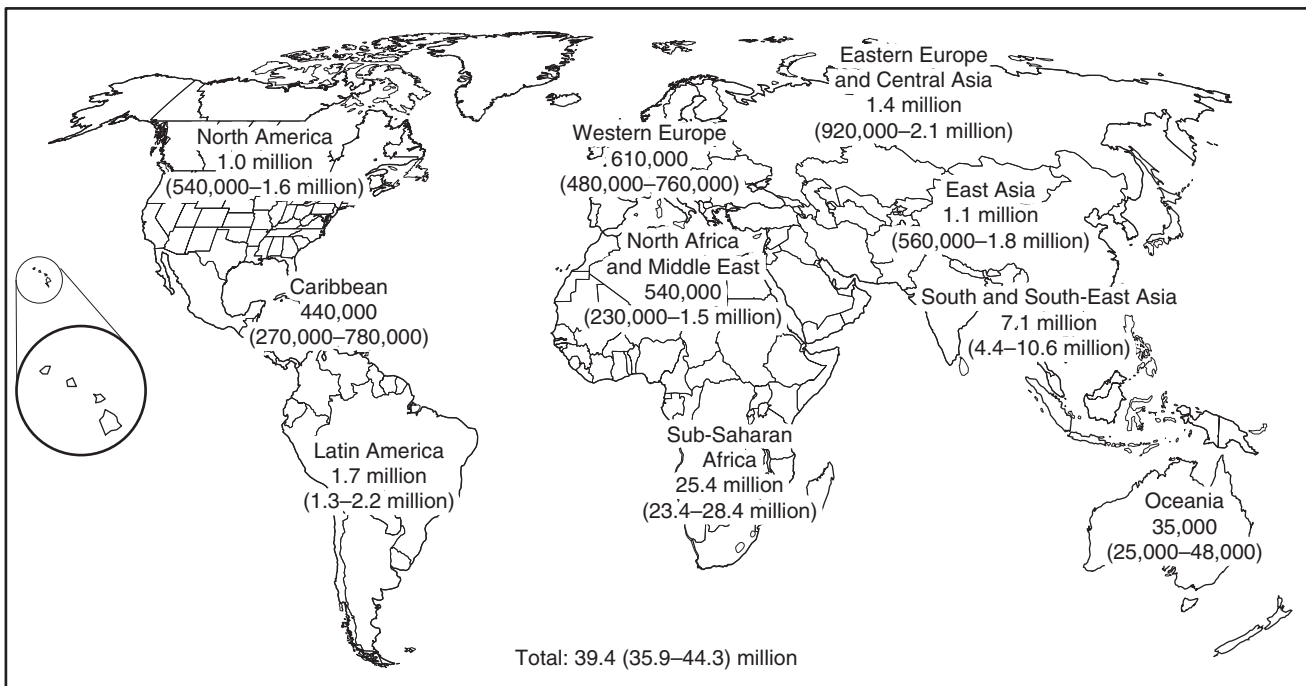

no symptoms, signs, or laboratory evidence of disease; “smoldering” or chronic T-cell leukemia, with an elevated percentage of abnormal lymphocytes; and full-blown ATL, with an elevated white blood cell count, anemia, and hypercalcemia. The overall natural history of disease in HTLV-I infection is slow, with an average of 20 to 30 years from the time of infection to the onset of ATL. Although less common, TSP and HAM can develop within a few years after infection. Although HTLV-II has been detected in a number of patients with lymphomas and other malignancies, it is still uncertain whether HTLV-II causes significant disease.

The prevalence of HTLV varies substantially in different parts of the world.<sup>101</sup> Highest prevalence, on the order of 35%, has been reported from Okinawa.<sup>102</sup> HTLV-I is also endemic in East Asia, Papua New Guinea, the Caribbean, and equatorial Africa, where prevalence of 1% to 10% is common. As with other chronic blood-borne infections, HTLV can be transmitted from males to females or to other males by sexual intercourse, from mother to infant at the time of birth, and by blood transfusion or the use of contaminated needles.<sup>103</sup> High prevalence of HTLV-I and -II has been found in populations of IV drug users in the United States and Europe.<sup>104</sup> A variety of promising antiviral agents have activity against HTLV-I and -II in vitro, but none has proved beneficial in ATL, TSP, or HAM. Treatment of ATL is directed at induction of leukemia remission, and for TSP and HAM it is largely supportive.

### MAGNITUDE OF THE HIV PANDEMIC

In 2004, 4.9 million people became infected with HIV. Globally, 40 million people are currently living with HIV, and women now represent 50% of all infections and 57% of cases in sub-Saharan Africa due to increasing heterosexual transmission in both the developing and developed world<sup>11,105,106</sup> (Figs. 76-4 and 76-5). The number of deaths due to AIDS continues to grow yearly with an estimated 3.1 million people dying of AIDS in 2004.<sup>11</sup> In many countries, AIDS is erasing decades of progress in improving life expectancy. In sub-Saharan Africa, life expectancy is now 47 years instead of the 62 years expected without AIDS (Fig. 76-6). In this setting, the death toll continues to rise with an estimated 68 million people dying earlier than they would have in the absence of AIDS in the 45 most affected countries. AIDS has a particularly strong impact on under-5 year mortality with most children who are infected at birth or through breastfeeding dying of AIDS before age 5. The majority of newly infected adults are under 25 years of age, and 90% of all new infections are occurring in developing countries. With an associated mortality rate greater than 90% and with the current lack of vaccine or curative drug, it is clear from these estimates that the HIV pandemic will continue to escalate worldwide and have an enormous impact on public health over the next several decades.<sup>10</sup>

Currently, the largest number of HIV-infected persons is in sub-Saharan Africa, totaling 25.4 million, and in Asia and the Pacific, totaling 8.2 million<sup>11,12</sup> (see Fig. 76-4). The epidemic in South Asia continues to be dominated by India, where an estimated 5.1 million infections were noted as of October 2003.<sup>107</sup> Although there is uncertainty about the future spread of HIV and its ultimate global dimensions, some short-term projections indicate that the incidence of HIV will increase by

**FIGURE 76-4** Estimated number of adults and children living with HIV as of the end of 2004. (Data from UNAIDS Program.)

**FIGURE 76-5** Growth of the global AIDS epidemic between 1990 and 2003 by prevalence and by number of people living with HIV/AIDS. (Data from UNAIDS Program.)

25% by 2005, with 45 million new infections occurring between 2002 and 2010.

## MODES OF TRANSMISSION

HIV infections are transmitted through unprotected sexual intercourse, including heterosexual and homosexual transmission; parenteral transmission, via blood through use of inadequately sterilized needles, syringes, or other skin-piercing instruments and transfusion of infected blood; and perinatal transmission from an infected mother to her fetus or infant during pregnancy, delivery, or breastfeeding.

### Sexual Transmission

Globally, between 75% and 80% of all HIV infections in adults are transmitted through unprotected sexual intercourse.<sup>108</sup> Heterosexual intercourse accounts for more than 70% of global adult HIV infections and homosexual intercourse for a further 5% to 10%, though in specific regions these proportions differ. For example, the proportion of sexual transmission due to homosexual spread is much greater in North America, Europe, and Australia, whereas heterosexual transmission is by far more common in the developing countries.<sup>10,104,105,109,110</sup> As a result of heterosexual transmission in Africa, the male-to-female ratio of HIV infection is 1:1.4. Urban populations with consistently high rates of sexually transmitted diseases (STDs) and prostitution have the highest rates of HIV infection. Rates of infection among female sex workers range from 40% in Kinshasa, Zaire, to 80% in Nairobi, Kenya, and 88% in Butari, Rwanda.<sup>111</sup> Rural areas that are culturally more conservative, and where the incidence of STDs is much lower there appear to be lower rates of HIV infection also, although rural rates of HIV infection are rising in some areas of Uganda, Tanzania, and other countries.<sup>111–113</sup> Certain risk factors, such as promiscuity, anal intercourse, sex with infected persons, prostitution, and other behavioral factors appear to be responsible for an increased risk of heterosexual transmission.<sup>114</sup>

An epidemiologic synergy has been demonstrated between HIV and STDs that is related to both behavioral and biologic factors.<sup>115</sup> Epidemiologic studies from sub-Saharan Africa, Asia, Europe, and North America suggest that there is approximately a fourfold greater risk of becoming HIV-infected if a genital ulcer caused by syphilis, chancroid, or herpes is present, and a two- to threefold greater risk if other STDs, such as gonorrhea, chlamydia infection, and trichomoniasis, are present.<sup>115–122</sup> Despite the prevention efforts of the past decade, STDs continue to be significant public health problems in developed and developing countries. In 1995 it was estimated that 333 million new cases of curable STDs, including gonorrhea, chlamydia infection, syphilis, and trichomoniasis, occurred.<sup>123</sup> An even greater number of cases may have occurred among the viral STDs, which include human papillomavirus, herpes simplex virus, and hepatitis. Of note, the greatest number of these STDs occur in Southeast Asia and sub-Saharan Africa, the two regions with the highest rate of HIV infection.

### Perinatal Transmission

With the increased incidence of HIV infection among women, perinatal transmission (which can occur in utero, during delivery, or postnatally via breastfeeding) is becoming increasingly common.<sup>124</sup> Serologic surveys, particularly in urban centers of sub-Saharan Africa, have found HIV infection rates of 5% to 30% in pregnant women<sup>125</sup> (Fig. 76-7). Transmission rates from mother to infant have been highly variable but range from 13% to 52%, with an average of 30%.<sup>126</sup> Factors associated with increased perinatal transmission include advanced maternal stage of disease, increased viral titers, decreased maternal serum vitamin A levels, chorioamnionitis, placental malaria, maternal anemia, maternal smoking, and low neutralizing antibody titers to the V3 loop of the glycoprotein gp120 of HIV.<sup>124,127–131</sup> The more common use of breastfeeding in developing countries may also contribute to the observed increased perinatal transmission in those countries compared with that observed in

**FIGURE 76-7** Median HIV prevalence in pregnant women attending antenatal clinics in sub-Saharan Africa, 1997–1998 to 2003. Data are from consistent sites. (Data from UNAIDS Program.)

developed countries; data suggest that up to 15% of infants breast-fed by HIV-infected mothers may become infected through breastfeeding.<sup>132</sup> Although bottle feeding is recommended for HIV-infected women in developed countries, this has not been recommended in developing countries, where breastfeeding helps prevent diarrhea and provides important nutrients for infants.<sup>133</sup>

### Parenteral Transmission

The sharing of HIV-infected injection equipment by illicit drug users results in about 5% to 10% of all adult infections.<sup>134</sup> In some areas of the world this is the dominant mode of HIV transmission, but in most developing countries, transfusion of HIV-infected blood or blood products still accounts for some adult HIV infections.<sup>135</sup> In many parts of the developing world, HIV screening of the blood supply is still severely limited because of cost. In areas where universal screening of blood donations has not been implemented, progress toward a safer supply of blood and blood products can be achieved through appropriate selection and retention of voluntary, nonremunerated, low-risk donors and through more rational use of blood aimed at decreasing the number of people receiving transfusions, as well as using blood substitutes and plasma expanders wherever possible.<sup>135–139</sup>

Other modes of transmission are more infrequent. For example, the risk of HIV transmission in a health care setting through accidental exposure to HIV-infected blood is estimated to be 0.3%, and the risk after mucocutaneous exposure is much less.<sup>139</sup> Household transmission may also occur when there is contact with blood or other body secretions or excretions from a person already known to be infected with HIV.<sup>140,141</sup> However, surveys done in Africa, Europe, and North America have shown that aside from sexual transmission within the household, nonsexual contact results in very few transmitted cases.<sup>141–143</sup>

### Biologic Factors Influencing Transmission

Most humans are fully susceptible to HIV infection. Some persons lack the second (chemokine receptor CCR5) cellular receptor for HIV attachment and appear to be naturally resistant to infection.<sup>79</sup> Such homozygous naturally insusceptible persons are rare in the United States; surveys have not yet been done among populations in tropical regions. Other persons may acquire immunity: some highly exposed, but apparently uninfected, individuals have measurable cellular immunoresponsiveness to HIV, suggesting that they have been immunized through repeated exposure to low levels of antigen or virus, but it is unknown whether they are truly immune to challenge.<sup>144,145</sup>

The co-occurrence of other sexually transmitted diseases, such as syphilis, chancroid, gonorrhea, and chlamydia infection, increases both the risk of acquisition and the risk of transmission of HIV infection. The exact mechanism of this increased risk is uncertain. Treatment of the STDs appears to lower the risk. Other local genital tract factors, such as male lack of circumcision, intercourse during menses, use of vaginal desiccants, and use of oral contraceptives, have in some studies<sup>146–149</sup> been associated with an increased risk of sexual transmission.

The level of virus in the blood and in genital secretions is probably an important biologic determinant of transmissibility. Some asymptomatic persons with low levels of infection (less than 100 genomes per milliliter of plasma) may never or only rarely transmit infection, while others with high levels (100,000 or greater) may be relatively efficient transmitters. In maternal-infant transmission studies, maternal viremia is a good, but not perfect, predictor of transmission risk. Genital tract excretion of virus has been reported to be inconsistent and intermittent in HIV-infected persons. However, the relationships between blood viremia levels, genital tract virus levels, and transmissibility are not well established.<sup>150–154</sup>

Viral genotype is another potential determinant of transmissibility. Biologic differences between genetic types have been most convincingly demonstrated in comparative studies of HIV-1 and -2 in West Africa. Blood viral loads, disease progression, and maternal-infant transmission are all much lower for HIV-2 than for HIV-1, but direct comparative studies of virus in genital tract or heterosexual transmission have not yet been done.<sup>155,156</sup> Other studies have focused on the possible differences between HIV-1 genotypes. Because the HIV-1 B clade is regularly associated with WHO pattern I transmission (men having sex with men and IV drug use), whereas the HIV-1 E clade (CRF01\_AE) is associated with pattern II (heterosexual sex), one study was done to compare the growth of HIV-1 B clade versus E clade virus strains in skin Langerhans' cells cultured *in vitro*. Langerhans' cells are thought to be the initial cells infected in the genital tract. E clade viruses were reported to preferentially grow in the Langerhans' cells, whereas B clade viruses grew well in T lymphocytes.<sup>157</sup>

### Global Molecular Epidemiology

Molecular epidemiology of HIV genotypes reveals the global pandemic comprises multiple, genetically distinct virus subepidemics.

The first clue to the nonrandom distribution of HIV strains around the world came from studies of HIV-2. Prevalence is highest in the contiguous West African countries of Guinea-Bissau, Gambia, Senegal, and the Cape Verde Islands (in the Atlantic Ocean 500 km off the western tip of Africa). Other countries with relatively high HIV-2 prevalence are Angola, Mozambique, Southwest India, Brazil, and Portugal.<sup>119,120,158,159</sup> All these countries were the sites of former Portuguese colonies. Portuguese sailors established a settlement just off Dakar, Senegal, in the 1400s, which remained in Portuguese control until it was taken over by the French in the 1600s. The Cape Verde Islands were uninhabited until settled in 1460 by the Portuguese, who then brought West Africans as slaves to the islands. Slave trade to the colonies was an important commercial activity in the Cape Verde Islands throughout the sixteenth and seventeenth centuries. It is uncertain when HIV-2 disseminated through the social networks built on the former Portuguese connections. It is possible that global dissemination of HIV-2 may have occurred as long ago as 400 years ago at the height of the slave trade, but there are no reliable data to resolve the issue.

More recent studies of genotyping of HIV-1 strains collected from around the world show that the prevalence of different clades in different countries is strikingly nonuniform.<sup>160</sup> Clade B predominates in western Europe and in North America; clades A

and D predominate in most of sub-Saharan Africa; clade C predominates in southern Africa, the Horn of Africa, and West India, and clade E/A predominates in Southeast Asia. HIV-1 genotypes A through H have all been detected in the equatorial African region bounded by Congo, Cameroon, Gabon, and the Central African Republic. The “cosmopolitan” clade B predominates in other regions of the world, where prevalence is for the most part lower and transmission is largely associated with men who have sex with men and IV drug users, such as South America, Australia, Japan, and China. HIV-1-O and HIV-1-N strains have been detected only in Cameroon, Gabon, and Equatorial Guinea and from persons with direct ties to these countries.

The Southeast Asian epidemic of the E/A clade was detected and studied relatively quickly. The earliest viral specimens from persons infected in northern Thailand (collected in 1990) all showed remarkable genetic homogeneity, consistent with a clonal epidemiologic origin (i.e., introduction by a single person).<sup>161</sup> This clonal epidemic has rapidly expanded to involve over 2 million persons. Clade E/A recombinants are also prevalent in equatorial Africa, where the genetic diversity of these viruses is substantial. These data suggest that the E/A epidemic in Southeast Asia was introduced from Africa.<sup>162</sup> Other studies of the diversity of the C clade viruses in western India, and F viruses in Brazil and Romania, suggest clonal epidemic origins.

Collectively these data show a pattern of global spread of HIV-1 that is irregular and unpredictable. The global epidemic cannot be characterized as a single emergence in Africa and steady gradual worldwide spread. A number of genetic variants have evolved in equatorial Africa, and at least five of these variants have seeded major clonal epidemics outside this region.

### Global Statistics and Projections

A total of 3.1 million deaths due to AIDS were formally reported to the WHO and UNAIDS by end of 2004, compared with 2.7 in 2002.<sup>11</sup> Southern Africa accounted for one third of all deaths due to AIDS globally. Underdiagnosis and underreporting both contribute to the low total of reported AIDS cases. More effort has gone into monitoring the prevalence and incidence of HIV infection rather than AIDS. From an epidemiologic point of view, this makes more sense, since AIDS cases are HIV infections that occurred 5 to 15 years earlier. HIV prevalence is determined by collecting data from serosurveys among a variety of high- and low-risk populations and extrapolating to the entire population of the country. Serial surveys in similar populations over many years—such as blood donors, military recruits, and women attending antenatal clinics—can also provide rough information about local incidence rates. Using all available data, including household surveys, to arrive at HIV estimates ensured the best possible quality. On the basis of such data from hundreds of surveys worldwide, WHO–UNAIDS estimated that there were approximately 40 million HIV-infected persons worldwide in 2004 compared with about 36 million in 2002., with incidence and prevalence rising most rapidly in East and Central Asia and Eastern Europe. While HIV-1 prevalence is continuing to increase in many tropical countries, infections have plateaued and may be declining in some industrialized countries.

Because the global epidemic is expanding most rapidly in Asia, where HIV-1 clades C and E/A predominate, clades C

and E/A are rapidly becoming the most common genotypes worldwide. Clade B viruses, prevalent in North America and Europe (and consequently the virus clade on which most laboratory research has been done), are among the less common variants worldwide.

Over the past two decades, the benchmark reporting systems for AIDS and HIV have changed radically. In the 1970s the epidemic spread silently and nothing was measured; in the 1980s clinically manifest AIDS cases were counted; and in the 1990s HIV prevalence and incidence were widely measured. Public health responsiveness during each of these decades changed correspondingly: in the 1970s ignorance prevailed because no one was aware that an epidemic had begun; in the early 1980s the response was arguably backward-looking, since decisions were driven by the number of AIDS cases; and not until the late 1980s and 1990s was the public health response fully informed in real time by the use of HIV-1 testing. It seems likely that as national and international public health systems continue to evolve, they will become forward-looking so that truly preventive steps will be routinely implemented in high-risk populations even before HIV-1 epidemics erupt.

### REGIONAL EPIDEMICS

There are wide variations in HIV prevalence throughout the world. Countries in sub-Saharan Africa and the Caribbean have the highest national rates of adult HIV prevalence.<sup>163</sup> At the end of 2001, adult prevalence ranged from approximately 0.1% in East Asia and the Pacific to more than 20% in seven African countries (Botswana, 38.5%; Zambia, 21.5%; Zimbabwe, 33.7%; Namibia, 22.5%; South Africa, 20.1%; Swaziland, 33.4%; and Lesotho, 31.0%).<sup>164</sup> Part of this disparity can be attributed to the maturity of the epidemics in Africa and the more recent introduction of HIV into central and eastern Asia; often the age of the epidemic in a given country can be gauged by the level of HIV seropositivity in that country. The high prevalence of HIV infections in Latin America, the Caribbean, and sub-Saharan Africa are also reflected in the distribution of AIDS cases in these regions. The United States has the highest reported number of AIDS cases, but underreporting in many developing countries makes the actual reports more unreliable from these regions. Consequently, the estimate of the number of AIDS cases is frequently based on the seroprevalence of HIV infection in these regions. Unfortunately, data regarding incidence or spread of HIV are scarcer but are urgently required to better estimate the future scope of the epidemic. The following section reviews HIV prevalence data for countries in the tropics.

#### Sub-Saharan Africa

By the end of 2003, 25.4 million adults in sub-Saharan Africa were living with HIV infection<sup>163</sup> (see Fig. 76-4). Sub-Saharan Africa accounts for only 10% of the world's population but nearly two thirds of the people living with HIV.<sup>11</sup> Three broadly defined geographic areas, which include countries with severe epidemics and others with epidemics at intermediate stages, account for almost 90% of all current HIV infections in adults and adolescents in Africa.<sup>163</sup> There is tremendous diversity across the continent with respect to

HIV prevalence rates with the lowest rates observed in West Africa with no country having a prevalence rate above 10%. All countries in southern Africa by contrast have prevalence rates above 17%, with Botswana and Swaziland having some of the highest prevalence rates on the continent, both over 35%. Population mobility, patterns of sexual behavior, and societal factors have likely influenced the diversity in HIV rates observed across the African continent.<sup>114,160</sup>

The transmission of HIV in sub-Saharan Africa occurs essentially through heterosexual contact. Rates of HIV infection among sex workers are variable but are as high as 80% in Nairobi and 55% in Abidjan.<sup>111,112</sup> Similarly, male clients of sex workers and clients of STD clinics have demonstrated increased rates of HIV infection, ranging from 5% to 30%.<sup>125</sup> The presence of behavioral factors and the biologic influence of STDs appear to facilitate the rapid transmission of HIV.<sup>115–119</sup> In addition, the lack of circumcision in males has been shown to add to the risk of HIV acquisition.<sup>161,162,165–167</sup> The rates of newly acquired HIV infection are highest in 15- to 24-year-olds,<sup>168</sup> a consequence of the predominant heterosexual mode of transmission in these countries. In addition, the peak of new infections occurs several years earlier in young women than in men. In Masaka, Uganda, the prevalence of HIV infection in 13- to 19-year-old females is 20 times higher than in males of the same age; however, the prevalence steadily increases in men, peaking at ages 5 to 10 years older than in women. In sub-Saharan Africa, there are 13 HIV-infected women for every man. This number is exaggerated among women aged 15 to 24 years, with 45 women infected for every 10 men in Kenya and Mali.<sup>11</sup> These epidemiologic findings appear to reflect the pattern of sexual behavior in these countries.

Within each country the HIV epidemic has progressed differently in various population groups. Early in the evolution of the epidemics, urban populations and rural communities located along highways were more rapidly affected. Urban and trading centers continue to have substantially higher prevalence of HIV infection than rural areas, but this pattern is by no means universal; population displacement, armed conflicts, and proximity to highways where intense migration and population mobility occur for economic reasons have strongly influenced the spread of HIV.<sup>114,160</sup> Some rural communities in Kenya, Tanzania, and Uganda have infection rates similar to those observed in neighboring urban populations. Following similar patterns of spread and intensity, HIV epidemics have recently expanded in Botswana, Lesotho, Swaziland, Namibia, Zimbabwe, and South Africa.<sup>11,163</sup> In other countries, perhaps with poorer transport networks, this has not been the case.

HIV seroprevalence surveys have generally been conducted on high-risk populations and pregnant women attending antenatal clinics; the latter provide a better assessment of the general dissemination of HIV in the population (Figs. 76-7 and 76-8). As of 2004, 17 African countries had prevalence rates above 10% in women attending the antenatal clinics surveyed in urban settings, with rates exceeding 40% in some sites.<sup>164</sup> In other sub-Saharan countries the HIV epidemic is in the intermediate stage, with between 1% and 10% of women attending antenatal clinics being infected with HIV. A few of these countries still have relatively low levels of HIV prevalence, but these have begun to rise in several countries such as Nigeria and Cameroon.<sup>11,163</sup>

**FIGURE 76-8** HIV prevalence among 15- to 49-year-olds in urban and rural areas in selected sub-Saharan African countries, 2001–2003. Burundi: population age is 15 to 24 years. Mali: population age is 15 to 59 years. South Africa: urban data from urban formal data and informal sectors; rural data from tribal areas and farms. (Data from UNAIDS Program.)

The observed high rates of HIV in women of reproductive age have resulted in high numbers of HIV-infected newborns. Of the 3 million infants in the world born with HIV infection since the beginning of the pandemic, over 90% have been born in Africa.<sup>163,169</sup> Typically, most of these children develop AIDS and die within a few years.

In addition to HIV-1 infection, HIV-2 is primarily found in West Africa with the exception of its presence in Angola and Mozambique.<sup>170,171</sup> The highest prevalence of HIV-2 infection is in Guinea-Bissau and in southern Senegal. In contrast to the increasing spread of HIV-1 throughout all of sub-Saharan Africa, the prevalence of HIV-2 has remained rather stable in West Africa and nonexistent in most other countries of Central and East Africa.<sup>172–174</sup> This has been partially explained by the higher infectiousness of HIV-1 compared with HIV-2.<sup>175</sup> The likelihood of transmission of HIV-1 through heterosexual intercourse is estimated to be about three times higher per exposure than for HIV-2. In addition, perinatal transmission rates of HIV-2 are reported to be significantly lower, less than 4%, than for HIV-1 (25% to 35%).<sup>176</sup>

In terms of further HIV spread, the consequences of contemporary political and civil unrest and subsequent population displacement such as those that occurred in 1994 and 1996 in the countries of the lakes region in Africa are particularly troubling.<sup>11,169</sup> Rwanda and Burundi, for example, already have one of the oldest and most severe HIV epidemics in Africa. HIV seroprevalence rates of over 20% among pregnant women and 50% among STD clinic patients are common.<sup>164,111,169</sup> Civil war in Angola has likely contributed to an alarming rise in HIV prevalence rate among pregnant women attending urban antenatal clinics in Luanda. In 2001, 8.6% of the women were HIV-positive compared with 1.2% in 1995.<sup>164</sup> With migration and displacement it is expected that these rates may be increasing in other areas as well.<sup>114,160</sup> In contrast, the Democratic Republic of Congo (DRC) to date has experienced a relatively low, stable HIV prevalence. The prevalence of HIV infection in Kinshasa has continued to be

4.1% in pregnant women attending urban antenatal clinics.<sup>164</sup> However, in view of the political events of 1996 and 1999 and the fact that DRC, with a population of 50 million, is one of the largest African countries, the HIV epidemic in that country may change rapidly with unpredictable and disastrous consequences.<sup>163</sup>

AIDS has emerged as the leading cause of death worldwide, surpassing tuberculosis for the first time in 1999. In 1998, 19% of all deaths in Africa were due to AIDS.<sup>177–180</sup> Excess deaths attributable to HIV infection are highest in 25- to 35-year-olds, an age group that usually has a low mortality. Nearly 90% of deaths in this age group were in excess of background rates and were attributable to HIV infection. The fact that many AIDS deaths occur in children and young adults has resulted in a substantial reduction in life expectancy, by more than 20 years in several countries (see Fig. 76-6). It is projected that population growth will decline more rapidly than expected and the size of the African population in the year 2025 will certainly be smaller than it would have been without AIDS.<sup>164,169</sup> However, because many adults bear children (often without AIDS, thus destined to be orphaned) before dying of AIDS, the population growth continues at an alarming 2% to 3% per year (i.e., doubling every 29 years or so). The increasing number of HIV infections and AIDS cases have already overwhelmed the capacity of urban health systems in some countries. In this regard, it is estimated that 80% of hospital beds in an infectious disease hospital in Abidjan, Côte d'Ivoire, and 50% in a hospital in Kampala, Uganda, are occupied by people with HIV infection. Demands for care will increasingly fall on poorly equipped and underfunded rural services, households, and individuals.

Demographic surveys in several countries have already noted significant increases in infant and child mortality.<sup>181–183</sup> Projections for Zambia and Zimbabwe indicate that AIDS may increase child mortality rates nearly threefold by the year 2010.<sup>169</sup> Owing to high levels of fertility, populations will generally continue to grow, but the critical deficits will be seen in the economically active ages. In countries where 8% of the adult population is HIV-infected, surveys have measured a doubling of mortality due to HIV and a decrease of at least 5 years in life expectancy. In 1995, UNAIDS examined the demographic impact of HIV infection and AIDS in 15 sub-Saharan African countries with a prevalence of HIV infection of more than 1% of the adult population.<sup>108</sup> Below that level of prevalence, the epidemic's impact on the national demographic picture is insignificant. In the 15 countries analyzed, the combined population was estimated to be 2 million people smaller than expected. In the year 2005 it will be 11.6 million smaller (291.8 million vs. 303.4 million). As a result of the high fatality rate due to HIV infection and AIDS, life expectancy at birth decreased in these 15 countries from 52.8 to 49.6 years. In the 45 most affected countries, it is projected that by 2020, 68 million people will die earlier than they would have in the absence of AIDS.<sup>164</sup> Average life expectancy in sub-Saharan Africa has fallen to 47 years compared to an expected 62 years in the absence of AIDS. These HIV epidemics will have severe effects on the population age structure, indenting the population pyramid in the main contributors to social and economic development, namely, young adults. Since AIDS kills people in their most productive years, it ranks as the leading cause of potential

healthy life-years lost in sub-Saharan Africa.<sup>177</sup> In Abidjan, Côte d'Ivoire, it was estimated that 15% of adult male deaths and 17% of male years of potential life lost (YPLL) resulted from AIDS, whereas in women AIDS accounted for 13% of deaths and 12% of female YPLL.<sup>178</sup> In two community-based rural studies in the Masaka and Rakai districts of Uganda, mortality among HIV-infected adults was over 100 per 1000 person-years of observation (PYO), an order of magnitude higher than among adults not infected with HIV.<sup>179,180</sup> In both districts, the adult prevalence of HIV infection was 8% and 13%, respectively, and HIV infection was found to be the leading cause of death. In this regard, more than 80% of deaths in the 20- to 29-year-old age group occurred among those who were HIV-infected. As a result, AIDS will double or triple the adult mortality rate in sub-Saharan African countries from levels that were already eight times higher than in developed countries. In countries such as Uganda, with an estimated 1.3 million infected persons out of a total population of 17 million, AIDS looms as the predominant health problem of the entire population.

With regard to children, it is estimated that the HIV pandemic resulted in 500,000 childhood deaths in 2003.<sup>163</sup> Additionally, as of the year 2001, more than 14 million children under age 15 years have been orphaned as a result of the premature death of HIV-infected parents.<sup>163</sup> In a recent survey of child mortality in 10 central and eastern African countries, the death toll from AIDS in children under 5 years of age was found to be likely to rise from 159 to 189 per 1000 by the year 2000. Even for those children who escaped perinatal infection, survival rates will decrease because of the loss of one or both parents to AIDS. For each woman dying of AIDS in Africa, an average of two children are orphaned. Overall, infant and child mortality rates have increased by as much as 30% more than previously projected as a direct consequence of perinatal HIV infection. Consequently, pediatric AIDS is now threatening much of the progress that has been made in child survival in developing countries during the past 20 years.<sup>181</sup>

Care of and support for children orphaned by AIDS will be a growing concern throughout the region, and the social, economic, and demographic impact of AIDS will be enormous. For a country with a current prevalence of HIV infection of 8%, the expected increased demand for health care services ranges from 2.3% to 9.3%, depending on the state of development of its health care sector.<sup>182,183</sup> The strong association of HIV with a burgeoning tuberculosis epidemic combined with the excess mortality associated with HIV infection underscores the critical importance of the HIV epidemic in Africa.<sup>184</sup>

### North Africa and the Middle East

This region represents 20 countries, with an estimated 480,000 individuals living with HIV.<sup>11</sup> Information on HIV infection in this region is limited, particularly among high-risk groups such as IV drug users. The highest prevalence of HIV infection in this region has been observed in Sudan, with 2.6% HIV prevalence representing almost 90% of the infections in this region.<sup>164</sup> The majority of infections in this region appear to be focused on injection drug users, although there is concern that HIV may be spreading undetected among men who have sex with men, as homosexuality is highly

condemned and illegal in many places. The future size and trends of the epidemic in this region are difficult to predict because of several factors: recent introduction of the virus, the status and disempowerment of women in society with associated decreased access to health care, the highly stigmatizing nature of STDs and the difficulties in their diagnosis and treatment, and the difficulty of conducting effective sexual health programs, often because of religious beliefs.

## Asia

Asia, where HIV has more recently been introduced, is in the early phases of an explosive HIV infection and AIDS epidemic. Since more than 60% of the world's population lives in Asia, the HIV epidemic could affect more people in this region than in any other area of the world.<sup>21,22</sup> For example, despite the fact that HIV was introduced into this region in the late 1980s, there are already 7.6 million adults living with HIV infection or AIDS.<sup>164</sup> The overall adult prevalence of HIV infection, however, is less than 1.0% because of the large population of these countries.<sup>164</sup> Thus, on a per population basis, although more people may actually be infected with HIV in Asia, AIDS may still have a greater impact in sub-Saharan Africa. The epidemic, however, is spreading rapidly in Asia with sharp increases in new infections in China, Indonesia, and Vietnam and an estimated 1.1 million new infections occurring in the region in 2003.<sup>11</sup> Countries such as the Philippines, Singapore, North Korea, and South Korea have had only limited spread to date and the rate of growth appears to be substantially lower.<sup>10</sup>

The pattern of HIV spread in Asia appears to be mainly concentrated among injection drug users (IDUs), men who have sex with men, sex workers, clients of sex workers, and their immediate partners. HIV infection was initially noted among IDUs in Thailand and in Manipur, northeastern India; seroprevalence rose from 55% to 80% in IDUs.<sup>185–189</sup> Recent data in the Yunnan province of China bordering Burma and Laos and considered part of the “golden triangle” of heroin exportation also demonstrate an alarming prevalence of HIV infection of 43% to 82% in IDUs.<sup>190</sup> Data from Malaysia and Vietnam show similar increases in IDUs. Concomitant with this rise of HIV infection among IDUs, HIV infection was noted among female sex workers; although highly variable by region, prevalence rates of 30% to 65% have been reported among female sex workers in various cities of Thailand and India.<sup>189,191</sup> Successive waves of heterosexual transmission from these sex workers to their male clients, and subsequently to other sex partners, including spouses, have resulted in the rapid spread of HIV to the general population.<sup>185,186</sup> Across Asia, effective prevention efforts have been hampered partly because of stigma and discrimination of the affected groups. HIV seroprevalence in India is high in the south and west. For example, in Bombay, prevalence increased from 2% in STD clinic attendees before 1990 to 36% in 1994.<sup>189</sup> The prevalence in sex workers rose from 1% to 51% between 1987 and 1993, and 2% of women attending antenatal clinics were positive in 1994.<sup>163</sup> In Pune, the overall HIV seroprevalence in 2800 STD clinic attendees was 23.4%.<sup>192</sup> Among initially seronegative persons, the subsequent incidence of HIV infection was 26.1 per 100 PYO for female sex workers, 9.4% for men, and 8.4% for women who were predominantly spouses of the

men attending these clinics.<sup>193</sup> Recently, unsafe sex between male-male sex partners has emerged as an additional important risk factor in the Indian epidemic.<sup>194</sup> As in Africa, recurrent genital ulcer disease, urethritis, or cervicitis was independently associated with an increased risk of seroconversion.

There is great geographic variation of HIV infection in India. Studies among sex workers in Calcutta have consistently demonstrated a low prevalence of 1.2%; in Vellore, women attending antenatal clinics have a prevalence of 0.1%. Many factors, including the prevailing sexual practices, a large population of HIV-infected female sex workers, the low social status of women, male patronage of sex workers, high rates of STDs, low rates of condom use, and the high number of IDUs in the north, make it likely that HIV will continue to spread in India and Thailand, as well as in many other populous countries.<sup>10</sup> India has the highest burden of infection in Asia, with an estimated 5.1 million adults and children infected with HIV, making it second only to South Africa in terms of absolute burden of infections.<sup>107</sup> As in Africa, the HIV epidemic is strongly associated with increasing spread of tuberculosis.<sup>195–198</sup> In India an estimated 1 to 2 million cases of tuberculosis occur every year. In Bombay 10% of the patients presenting with tuberculosis are now HIV-positive. Tuberculosis is also the presenting symptom of AIDS in more than 60% of AIDS cases. In Thailand public health authorities have noticed a marked increase in tuberculosis cases compared with a steady decline in previous years.<sup>199</sup>

HIV was introduced in Cambodia in the early 1990s and is predominantly occurring among heterosexuals with multiple sexual partners. To date there has been little evidence of a significant problem of injecting drugs in Cambodia. Levels among blood donors in Phnom Penh have risen, though, from less than 0.1% in 1991 to 10% in 1995. Dramatic rises have also been seen in sex workers, the military, STD patients, and pregnant women. Thailand and Cambodia have shown that early large-scale prevention efforts can change the natural course of the epidemic. Among pregnant women in major urban areas in Cambodia, the HIV prevalence declined from 3.2% in 1996 to 2.7% at the end of 2000.<sup>164</sup> The Cambodian government has implemented a multifaceted prevention program including a 100%-condom-use program and steps to counter stigma.

The epidemic in Myanmar is one of the more serious in the region. Although controversial and disputed by the government, estimates of prevalence rates as high as 3.46% (687,000 infected) have been reported.<sup>200</sup> This epidemic began primarily among IDUs in the late 1980s with a prevalence of HIV infection of 60% to 70% in 1992. HIV prevalence in sex workers, as in India and Thailand, has also steadily risen, from 4.3% in 1992 to 18% in 1995. In Malaysia, HIV infection levels in IDUs have also grown rapidly, from 0.1% in 1988 to 20% in 1994. Similarly, in female sex workers the rates have increased from 0.3% in 1989 to 10% in 1994. In Vietnam, HIV rates increased from 9% to 38% between 1992 and 1995. High levels have also been demonstrated in IDUs in treatment (32% in 1992–1995).

The epidemic in China has raised alarm, since it appears to be spreading into new groups of the population. Despite sketchy surveillance data, it is estimated that 850,000 Chinese were living with HIV/AIDS in 2001.<sup>164</sup> Several localized HIV epidemics are being observed among certain population

groups across China, highlighting the need for swift action if a more serious epidemic is to be prevented. The majority of early reported HIV infections have been among IDUs in Yunnan province (about 70%).<sup>191</sup> However, China is currently in what has been termed the expansive phase of its epidemic with infections spreading to partners of IDUs and blood donors and a steady rise in rates observed among sex workers.<sup>201</sup> Men who have sex with men, ignored in the official statistics, have also emerged as a high-risk group for HIV transmission. The number of infections in China more than doubled between 1999 and 2002.

## DISEASE

### Pathogenesis and Natural History

After many years of debate on the hypothesis that AIDS is fundamentally an autoimmune disease, it is now clear that autoimmunity is not an essential component of the pathogenesis (Fig. 76-9). Instead, disease progression is a direct reflection of virus replication.<sup>202,203</sup> In the absence of active viral replication, or when viral replication is low (blood viremia levels less than 100 genome copies per milliliter), HIV infection does not progress to clinical immunodeficiency. Conversely, when viral replication is rapid (viremia greater than 100,000 genome copies per milliliter), disease progression is correspondingly rapid. Treatments with antiviral drugs slow disease progression in proportion to their effect in lowering viremia levels. The course of HIV infection can be quite variable. The initial infection is followed by an eclipse phase in which neither viremia nor an antibody response can be found. A virologic “primary infection” with high levels of viremia then appears and persists for several weeks.<sup>204</sup> Up to 30% of HIV-infected persons are reported to experience a mononucleosis-like syndrome of fever, pharyngitis, rash, and depressed CD4+ cell counts during this primary infection. However, in many careful studies the proportion showing symptoms during primary infection is much lower than this.<sup>205,206</sup> There are no published studies on symptomatic primary infections with HIV strains in tropical countries or with genotypes other than clade B.

**FIGURE 76-9** Diagram of the natural history of HIV infection in a “typical” case showing changes in the CD4+ cell count and the plasma RNA copy number over a span of 10 years.

Among HIV-infected patients studied in the United States and Europe, most progress from infection to AIDS in 5 to 15 years. A fraction of patients, about 5% to 10%, progress more rapidly (rapid progressors), and another fraction, perhaps 5%, show no evidence of progression over many years (non-progressors).<sup>207–209</sup> In HIV-1–HIV-2 studies, HIV-2 infection invariably produces a lower viremia than does HIV-1 and HIV-2 also shows a much higher proportion of nonprogressors. Few rigorous natural history studies have been done in tropical countries or in regions where HIV-1 genotypes other than clade B predominate. One study of HIV-1 infections among commercial sex workers in Kenya showed rapid progression to AIDS (within 5 years) in 50%.<sup>210</sup> It is uncertain whether the high proportion of rapid progressors in this study in Africa can be attributed to the prevalent viral genotypes (probably clade A and clade D), to the high prevalence of aggressive opportunistic infection (e.g., tuberculosis), to the lack of optimal medical care, or to poor nutrition or other host factors.

There is no evidence that the virus in rapid progressors is more virulent than average. Instead, natural history studies suggest that rapid progressors mount an inadequate immune response. Most patients show low or absent antibodies or cellular responses. Rarely, rapid progressors have been described who appear to be completely but selectively unresponsive to HIV antigens. Because these patients lack HIV antibodies, they can pose a diagnostic challenge.

Nonprogressors typically have low plasma viral titers. In some nonprogressors, low viral titers are due to infection with grossly replication-defective virus, but in most patients it is uncertain whether low viral titers reflect viral factors (poor replication), host genetic factors, or an unusually strong immune response.<sup>211</sup> Nonprogressors do routinely show strong immune responses to HIV proteins, including antibody and cellular responses, but it is unclear if this is cause or effect.

### Mechanism of Immune Dysfunction

Depletion of CD4+ T lymphocytes is the central mechanism of immune dysfunction by HIV. Progressive depletion is a consequence of a furious rate of viral replication in these cells. The turnover rate of CD4+ T lymphocytes—their destruction and replenishment—is correspondingly turbulent. Each day in an infected patient, up to 10<sup>9</sup> new virions are made and about 10<sup>9</sup> CD4+ T lymphocytes are killed and replaced.<sup>212,213</sup> Loss of CD4+ T cells results in a loss of recognition of antigens that are presented on class II MHC molecules. Th1 function is especially damaged with loss of cell-mediated immune functions. Th2 functions are impaired as well with gradual loss of humoral responsiveness to newly presented foreign antigens. Loss of in vivo delayed-type hypersensitivity skin test reactivity to recall antigens such as *Candida*, mumps, and tetanus parallels the loss of cell-mediated immunity and the appearance of opportunistic infections.

Three major mechanisms of CD4+ T-lymphocyte killing by HIV have been suggested: direct virus-mediated cytolysis, virus-induced apoptosis, and indirect killing through immune effector mechanisms. Direct virus-mediated cytolysis has been demonstrated in vitro. Syncytium formation may accelerate the cytolytic process. Syncytium-inducing isolates appear in blood in the late stages of illness and are a poor

prognostic sign when present in earlier stages. However, the presence of syncytium-inducing virus isolates strongly co-varies with blood viral titer, so cause-and-effect relationships remain uncertain. Apoptosis may also contribute to cell destruction in vivo.<sup>214,215</sup> CD4+ T lymphocytes from infected patients undergo apoptotic death when stimulated in vitro. However, uninfected CD8+ as well as CD4+ cells from HIV-infected patients show increased apoptotic death. Apoptosis probably reflects the high rate of ongoing immune activation in HIV-infected persons and probably is not a principal cause of immune depletion. Immune destruction of infected cells also is not likely to be a central mechanism of CD4+ T-lymphocyte depletion: persons with weak immune responses show more rapid depletion and more rapid clinical disease progression. Other pathogenic mechanisms have been proposed, including induction of anergy by circulating soluble gp120 or by super-antigen stimulation of lymphocytes, and autoimmunity induced by HIV antigens cross-reactive with normal cell proteins.<sup>216</sup> These in vitro mechanisms have not been established to be important in vivo.

### Anti-HIV Immunity

Unlike in other infectious diseases, there is as yet no direct evidence that humans can become “immune”—in the classic sense—to HIV. Infection becomes chronic in everyone infected; no adults have spontaneously cleared their infection. Also, there is as yet no direct evidence that any candidate HIV vaccine can render a person protected against subsequent challenge. Most HIV-infected adults do mount a vigorous antibody and cellular immune response to HIV. It is thought that this immune response, while insufficient to clear infection, is nonetheless sufficient to impede viral replication.

Serum antibodies to env, gag, pol, and nef appear in the blood of most HIV-infected patients within a few weeks to months after exposure to infection. Antibodies to tat, rev, and the other accessory proteins are also detectable in a variable proportion of patients. Antibody titers to all viral proteins fall as disease develops, and low anti-HIV antibody titer is a poor prognostic sign. In vitro, antibodies can block HIV replication through ADCC (antibody-dependent cellular cytotoxicity), killing of infected cells, or virus neutralization.<sup>217</sup> HIV neutralizing antibody activity can be measured by mixing dilutions of serum with a small dose of virus, then monitoring viral replication when the mixtures are inoculated into cultures of CD4+ T lymphocytes. HIV anti-envelope antibodies effectively neutralize viral growth. Neutralization serotypes of HIV-1 strains have been described, and these correspond to the genotypic clusters. Paradoxically, anti-HIV serum antibodies can increase the replication of HIV-1 in cultures of macrophages and other Fc receptor-bearing cells by facilitating the initial viral binding to the cell surface. It is uncertain whether this “antibody-dependent enhancement” of HIV-1 growth has in vivo significance.<sup>218,219</sup>

HIV-reactive lymphocytes are present in the blood of essentially all infected patients. Cultured patient CD4+ T lymphocytes proliferate when exposed in vitro to HIV envelope or gag proteins. The vigor of proliferation is maximal in the early, asymptomatic stages of infection and decreases as disease progresses. CD8+ anti-HIV class I MHC-restricted cytotoxic T lymphocytes (CTLs) with activity against HIV core, envelope,

polymerase, and nef proteins are also present in blood. Class II-restricted CTLs are also found. Appearance of CD8+ blood CTL activity correlates temporally with the initial fall of viremia, so it is thought that CTLs are important in control of replication through killing of infected cells.<sup>220–222</sup> CD8+ cells also release soluble factors that inhibit HIV replication through non-cytolytic mechanisms.

Once established, HIV infection never spontaneously disappears completely in adults. However, spontaneous “cures” have been reported in a few infected infants.<sup>223</sup> It is hypothesized that passively acquired maternal immunity was important in partially suppressing the infection in these infants. Self-curing abortive and suppressed infections have also been observed in SIV-vaccinated and -challenged monkeys.<sup>224</sup>

### Clinical Manifestations

A substantial proportion of patients with acute primary HIV infection (up to one half) may experience a mononucleosis-like illness characterized by fever, pharyngitis, and a slight morbilliform rash. Rarely, patients experience neurologic manifestations. In 80% to 90% of patients, the illness is so mild that medical care is not sought. Primary HIV infection is rarely seen in medical care facilities in tropical countries.

The early stage of chronic HIV infection is usually asymptomatic, with the CD4+ cell count remaining above 500 cells/mL. About half of patients have modest generalized lymphadenopathy. Autopsies on early-stage HIV-infected patients who die of non-HIV-related causes (e.g., automobile accidents) show HIV-1-infected cells in lymphatic tissues throughout the body.<sup>225</sup> At this stage a number of dermatologic conditions of uncertain cause may be present, especially seborrheic dermatitis, psoriasis, and folliculitis.<sup>226</sup>

Intermediate HIV disease, defined by CD4+ counts between 200 and 500 cells/mL, is also usually asymptomatic or at least without serious manifestations. Skin and mucosal opportunistic infections are common, including herpes zoster (shingles), herpes simplex, oral or vaginal candidiasis, oral hairy leukoplakia, and cervical dysplasia.<sup>227,228</sup> Bacterial infections caused by common respiratory tract organisms such as *Streptococcus pneumoniae* are increased, as is pelvic inflammatory disease. Patients may begin to experience fever, diarrhea, and weight loss. The occurrence of these intermediate manifestations, but without an AIDS-defining opportunistic infection or cancer, has historically been referred to as “AIDS-related complex,” or ARC.

Late-stage HIV disease, AIDS, is defined by a CD4 cell count below 200 cells/mL. The list of AIDS-defining conditions issued jointly in 1993 by the Centers for Disease Control and Prevention (CDC) and WHO is shown in Box 76-1.<sup>229</sup> This revision included three new AIDS-defining conditions that are more common in heterosexual patients, including recurrent bacterial pneumonia, cervical carcinoma, and pulmonary tuberculosis. This listing, while an improvement, still omits several HIV-related infections that are more prevalent in tropical countries. These include parasites (*Cryptosporidium*, microsporidia, *Cyclospora*, *Leishmania donovani*, and *Trypanosoma cruzi*); fungi (*Penicillium marneffei*); and bacteria (*Bartonella*, *Rhodococcus*). The issue is not merely academic, for in many countries the availability of social benefits and access to medical care depend on a diagnosis of an AIDS-defining illness.<sup>230</sup>

**Box 76-1** 1993 U. S. Centers for Disease Control–World Health Organization Classification of AIDS-Defining Conditions

- CD4 cell count <200/ $\mu$ L
- Candidiasis, pulmonary or esophageal
- Cervical cancer
- Coccidioidomycosis
- Cryptosporidiosis
- Cytomegalovirus infection
- Herpes esophagitis
- HIV encephalopathy
- Histoplasmosis
- Isosporiasis
- Kaposi's sarcoma
- Lymphoma
- Mycobacterial disease
- *Pneumocystis carinii* infection
- Pneumonia, bacterial
- Progressive multifocal leukoencephalopathy (polyomavirus)
- Salmonellosis

Many common tropical infections, including malaria, schistosomiasis, filariasis, onchocerciasis, cholera, yellow fever, and dengue have not been identified as HIV-related opportunistic infections. Two very prevalent diseases, malaria and African trypanosomiasis, have been studied and shown to have no relationship.<sup>231,232</sup> Nonetheless, the range of HIV-related opportunistic infections does vary in different regions of the world. Certain AIDS-defining infections common in the United States are diagnosed much less frequently in Africa and Asia, particularly *Pneumocystis carinii* pneumonia (PCP), *Mycobacterium avium-intracellulare* (MAI), and cytomegalovirus (CMV) disease. Other infections are more common in tropical countries, depending on the locally prevalent microbes.

In sub-Saharan Africa, diarrhea from cryptosporidiosis, isosporiasis, or microsporidiosis is common. In Latin America, cerebral toxoplasmosis, cryptosporidiosis and isosporiasis, Chagas' disease, and cutaneous and visceral leishmaniasis are common. Cases of HIV-associated disseminated strongyloidiasis and paracoccidiomycosis have also been reported. In Southeast Asia, disseminated infections with the dimorphic fungus *P. marneffei* are common.<sup>233</sup>

*Mycobacterium tuberculosis* (MTB) is the most common serious opportunistic infection worldwide. Clinically apparent tuberculosis can occur at any stage of HIV infection, but the risk increases with immunoincompetence. Five percent to 10% of persons co-infected with HIV and MTB develop active tuberculosis each year. The prevalence of tuberculosis in persons with AIDS in Latin America has been reported to be 17% to 30%; in Africa, 25% to 44%; and in Asia, 23% to 68%. Almost half of patients with the end-stage HIV wasting syndrome (slim disease) in Africa are shown at autopsy to have disseminated MTB.<sup>234</sup>

## DIAGNOSIS AND PROGNOSIS

Disease from HIV becomes clinically apparent only after years of asymptomatic infection and clinical signs, when they

do occur, are usually unspecific. Consequently, laboratory assays are essential to diagnosing HIV infection.

## HIV Antibody Assays

HIV antibody assays on blood serum or plasma are used to establish a diagnosis. The most common test is the ELISA. A variety of configurations have been developed and marketed, but plastic microtiter plates or beads are most often used as the solid-phase surface for adsorption of viral antigens. Patient antibodies that bind to viral antigens are detected with antihuman immunoglobulins tagged with enzymes. Readouts are obtained by color changes in a substrate fluid catalyzed by the enzyme.

Antibodies to HIV-2 and HIV-O are only partially cross-reactive with HIV-1 in most commercial ELISAs.<sup>235,236</sup> Although HIV-2 and HIV-O infections are rare outside certain well-described regions of the world, concerns about undetected HIV-2 among blood donors in the United States and Europe were sufficient to lead most manufacturers to develop and market HIV-1–HIV-2 combination ELISAs. Many current ELISAs also contain HIV-1-O antigens.

Specificities and sensitivities for most commercial ELISAs are said to exceed 99%. However, the positive predictive value of a repeatedly reactive ELISA on a single serum specimen will vary markedly depending on the true prevalence of HIV infection in the tested population. When used in a hospital laboratory in an HIV-endemic region, over 99% of repeatedly reactive specimens might be true positives. However, if exactly the same test kit was used for blood bank screening in a low-prevalence region, only 10% of repeatedly reactive specimens might be true positives.

The most effective strategy to deal with the problem of imperfect specificity of ELISAs is to confirm all positive ELISA results by testing repeatedly reactive specimens with a second assay of completely different design. Immunofluorescent assays and radioimmunoprecipitation assays have been used for this purpose, but the Western blot is most commonly used.<sup>237</sup> Western blot strips are prepared by electrophoresis of lysed HIV-1 viral particles through a polyacrylamide gel and blotting of the resultant viral protein bands of different molecular weights onto nitrocellulose paper. Anti-HIV antibodies in a specimen are detected with enzyme-tagged antihuman immunoglobulins. Western blots are read according to which viral bands show bound patient antibodies. Serum from HIV-infected patients usually has antibodies to all viral proteins, and interpretation of the blot is not difficult. However, incomplete banding patterns do occur and can lead to diagnostic difficulty.<sup>238,239</sup> Since 1989 blot interpretation criteria adopted by the CDC are most widely employed.<sup>240</sup> These criteria define a blot as reactive if antibodies are present to at least two of three of the following HIV structural proteins: the capsid p24 protein, the transmembrane envelope gp41 protein, and the surface envelope gp120 or gp160 protein.

Several rapid and simple HIV antibody assays have been developed that are intended for use outside laboratory settings. There are a variety of configurations, including agglutination of latex beads or red blood cells, or dot-blots on dipsticks. Antibodies are also present in body fluids other than blood serum, but at lower titers, and test kits have been developed and marketed that use urine or saliva. The sensitivity

and specificity of these alternative assays can be quite good but are generally below those of serum ELISA testing.

HIV antibody testing is most effective when an algorithm for assay use is thoughtfully designed and scrupulously followed. A variety of algorithms have been proposed, each appropriate for a particular health care setting. Optimal algorithm design will vary according to many local factors: the true prevalence of HIV infection in the population to be tested, the expected ratio of HIV-1 to HIV-2 infections, the availability of laboratory facilities, speed requirements, and cost constraints. Most algorithms include the following steps: (1) a screening assay, (2) repeat testing of specimens with positive screening assay results on the same specimen, and (3) supplemental testing with a second assay of different design. In very low prevalence populations, it is advisable to verify results by obtaining and testing a new serum specimen before a diagnosis is considered established. To avoid confusion, it has been customary to describe individual assay results as “nonreactive” or “reactive” and to reserve the terms “negative” and “positive” for the algorithm bottom-line conclusion.

Diagnosis of HIV infection in infants presents special problems owing to the presence of passively acquired maternal antibodies. One approach is to wait until maternal antibodies have waned (1 year) and then test for antibodies. Another is to test directly for HIV virus, antigens, or genome with viral cultures, p24 antigen assays, or DNA polymerase chain reaction (PCR).

### HIV Culture and p24 Antigen Detection

HIV can be isolated from blood plasma, peripheral blood mononuclear leukocytes (PBMLs), and lymphoid tissues in virtually all patients. The isolation rate is directly related to viral titer. The technique is expensive, labor-intensive, and relatively slow. Isolation is essential to certain types of laboratory research, such as measurement of antiviral drug sensitivity patterns. In the conventional isolation technique, normal healthy human donor PBMLs are stimulated with phytohemagglutinin and used as the culture substrate.<sup>241</sup> Patient specimens are co-cultivated with normal stimulated cells, and culture supernatants are monitored for up to 1 month for viral antigens (p24) or reverse transcriptase activity.<sup>242</sup>

HIV antigens also circulate in the blood of infected patients.<sup>243,244</sup> Commercial kits are available for measurement of HIV p24 capsid protein levels, which range from 50 pg/mL to 100 ng/mL. Much of the circulating HIV p24 antigen may be complexed with anti-p24 antibodies, so an immuno-complex acid dissociation step is necessary to improve sensitivity.<sup>245,246</sup> Serum p24 assays have been suggested as screening tests to detect HIV-infected, but antibody-negative, donated blood units. Because the antibody-negative “window” period following seroconversion is so short relative to the total duration of HIV infection, in most settings p24 antigen testing of specimens from adults adds little to antibody testing for purposes of detecting HIV infection. However, measurement of HIV p24 levels can give prognostic information. Serum p24 antigen levels are correlated with plasma viral titers and with serum genomic RNA levels. High serum p24 antigen levels portend a poor prognosis, and p24 antigen levels fall with effective antiretroviral therapy. HIV p24 antigen testing is rapidly being supplanted by detection and quantitation of HIV nucleic acids.

### Measurement of HIV Nucleic Acids

The PCR, in which strands of nucleic acid are amplified exponentially one strand to two, then four, then eight, and so on has revolutionized the diagnostic approach to the HIV infected patient. PCR can be used to amplify HIV sequences from cellular proviral DNA, from cellular RNA, or from HIV virions.

DNA PCR is useful in establishing a diagnosis of HIV infection in situations in which antibody testing gives ambiguous results.<sup>247</sup> Testing of infants of infected mothers (all of whom passively acquire maternal antibodies) is the most important use. DNA PCR can also be used to confirm HIV infection in persons with indeterminate Western blot results.

HIV RNA measurement with PCR requires an initial conversion of the viral RNA sequences to complementary DNA (cDNA). This is done by addition of exogenous reverse transcriptase (RT), followed by PCR amplification and then quantification of the specific DNA product.<sup>248,249</sup> Because errors can be magnified exponentially, RT-PCR must be carefully standardized and controlled. Measured quantities of control nucleotide sequences can be added directly into each test specimen tube, as in quantitative competitive RT-PCR, or controls can be run in parallel in separate tubes in each run. Both approaches have been optimized. Commercial RT-PCR test kits are designed to quantitate genomic HIV RNA in plasma, but the technique can be modified in research laboratories to measure various splice-classes of HIV RNA in cells or to measure HIV RNA in other fluids such as semen or cervical secretions.

The branch-chain DNA (bDNA) technique is an alternative non-PCR method of RNA detection.<sup>250</sup> In the bDNA assay, viral RNA is pulled out of a sample by HIV-specific DNA capture sequences onto a solid phase. Captured HIV RNA is detected by binding of DNA probe sequences, which in effect have long, branched DNA tails that are enzyme-tagged. Results are read by enzyme-catalyzed substrate changes.

Both RT-PCR and bDNA assays are expensive, about U.S. \$100 per assay. The bDNA assay is somewhat simpler to perform, but the RT-PCR method is more sensitive. In vivo HIV genomic RNA levels range from 10 to over 1 million copies per milliliter of plasma. The RT-PCR can approach this lower limit, but the bDNA assay can detect only down to 10,000 copies per milliliter. The RT-PCR technique is also preferred for many research purposes because a large quantity of amplified cDNA is produced.

The plasma HIV RNA level is a direct measure of in vivo HIV replication and is therefore a powerful prognostic tool. For any given untreated patient, the plasma viremia level remains relatively constant, or increases slightly, over several years. It appears that the “virologic script” for the disease course is “writ” very early after primary infection.<sup>251,252</sup> Patients with low viremia levels (100 to 1000 genome copies per milliliter) after seroconversion do well and are often nonprogressors, whereas patients with high viremia levels (100,000 or greater) do poorly and are often rapid progressors. Levels are typically quite low in HIV-2-infected patients compared with HIV-1-infected patients. There are as yet no reports of plasma RNA levels in developing countries where HIV-1 genotypes other than clade B predominate.

Nucleic acid amplification and detection techniques all require that the “quarry genome” sequence be known. Reagent nucleotide sequences (primer sequences and probe sequences

in RT-PCR, or capture sequences and probe sequences in the bDNA assay) must be highly homologous to the quarry genome sequence for the techniques to work at all. This is not a serious problem in the United States, where essentially all HIV strains are of the B clade. However, it has proved difficult to construct a single assay that can be used worldwide, including in other countries where other genotypes predominate.

### Immunologic Assessment of HIV-Infected Patients

The CD4+ T-lymphocyte count is the most widely used measure of HIV-induced damage to the immune system. In the United States, absolute counts of less than 200 cells/mL or a CD4+ percentage of less than 14% is strongly associated with an increased risk of opportunistic infections and is now accepted as definitional for AIDS.<sup>253,254</sup>

The CD4+ count can be performed manually and read visually, but usually it is done with an automated fluorescence-activated flow cytometer. CD4+ cell counts are vulnerable to biologic and technical errors. The main biologic error in CD4+ cell counts is attributable to a pronounced diurnal variation that can be up to 150 cells/mL in healthy adults but is usually less in patients with lower T-cell counts. This effect can be minimized by performing counts at a fixed time of day. Another common contributor to inaccurate CD4+ cell counts is simple errors in measuring the percentage of lymphocytes on a standard differential white blood cell count. Normal values for total CD4 cell counts, the percentage of lymphocytes that are CD4+ cells, and CD4+/CD8+ count ratios may differ among adults in different countries. Ideally, every clinician managing HIV-infected patients should know the local laboratory CD4+ count standard values and variability.

Delayed-type hypersensitivity skin testing is another method of assessing immune impairment. Healthy uninfected controls in the United States respond to a variety of common skin test antigens, including *Trichophyton*, mumps, tetanus, and *Candida*.<sup>255</sup> As HIV disease progresses, normal skin test reactivity to these common antigens is lost. Loss of skin test reactivity to *Candida* antigens correlates strongly with the appearance of clinical candidiasis. Skin testing with these antigens also provides a control for the tuberculin skin test response. The tuberculin skin test result interpretation may vary according to local prevalence. In countries where prevalence among healthy persons is high, a negative tuberculin response in an HIV-infected patient probably signifies anergy and a high risk of tuberculosis. Where possible, skin testing with control antigens should also be done in parallel with tuberculin testing. *Candida* reactivity is probably prevalent in healthy populations worldwide, but this has not been established, and antigens are not widely available. Local control antigens and values may be required.

Other markers of disease progression include serum  $\beta_2$ -microglobulin and neopterin levels, but these assays have relatively little clinical utility. Several staging and classification systems have been used in clinical patient management. The Walter Reed system uses CD4+ counts, skin test results, and clinical signs to define six stages with distinctive prognostic significance. The CDC (1993 revision) uses CD4+ counts and clinical signs to define nine categories. However, it now seems clear that patient prognosis and management can best be achieved with (1) a CD4+ cell count, which is the best marker

of immune damage, (2) a quantitative plasma viral RNA measurement, which is the best marker of active viral replication, and (3) clinical signs and symptoms.

### TREATMENT

Optimal medical management of the HIV-infected patient includes therapy with antiretroviral agents, prevention of opportunistic infections and cancers, and treatment of complications as they arise. Complete medical care includes counseling of patients and their families.

#### Antiretroviral Therapies

The first class of drugs proved to have clinically significant anti-HIV activity were the nucleoside analog reverse transcriptase inhibitors (NRTIs): zidovudine (AZT), didanosine (DDI), zalcitabine (DDC), stavudine (d4T), lamivudine (3TC), and abacavir (ABC) (listed here in order of their approval by the U.S. Food and Drug Administration [FDA]).<sup>256,257</sup> These drugs are phosphorylated by cellular enzymes to their respective triphosphate forms, which block reverse transcriptase by substrate competition with natural nucleosides and by chain termination of the growing DNA strand. As monotherapy these drugs show only modest clinical and antiviral effects. Major problems include prompt emergence of drug resistance and significant toxicities.<sup>258</sup>

The second major class of anti-HIV drugs are the non-nucleoside reverse transcriptase inhibitors (NNRTIs) such as nevirapine, delavirdine, efavirenz. Added to this list are tenofovir and Emtricitabine, nucleotide RT inhibitors. These drugs do not require modification by cellular enzymes but act by direct binding to sites on the reverse transcriptase. As monotherapy the NNRTIs show the same problems as the nucleoside analogs.<sup>259</sup> Clinical trials have shown that combinations of therapies—two or three nucleoside analogs or NNRTIs, or both—give more potent and lasting effects. Disease progression is slowed, but only on average by 1 or 2 years.<sup>260</sup>

The third class of antiretrovirals, the inhibitors of HIV protease, (saquinavir, indinavir, ritonavir, nelfinavir, amprenavir, lopinavir/ritonavir, atazanavir) have demonstrated clinical efficacy.<sup>261–264</sup> These drugs act by binding to and blocking the HIV protease enzyme that is essential to cleaving the gag-pol polyprotein. Combination therapy, usually referred to as highly active antiretroviral therapy (HAART), of reverse transcriptase inhibitors and protease inhibitors is synergistic, and some combinations have lowered plasma HIV RNA levels to undetectable levels. A newer drug, enfuvirtide (Fuzeon), in the class of fusion inhibitors (FIs), is now in use.<sup>265</sup>

Most studies of antiretroviral therapy of HIV have been done in industrialized countries, particularly North America and Europe. Limited in vitro screening of HIV isolates from other countries, and in particular genotypes other than clade B, has not found any obvious patterns of naturally occurring resistant viruses within the major group of HIV-1. Nevertheless, strains of HIV-1 group 0 and HIV-2 are naturally resistant to most NNRTIs. However, the price of chronic therapy with antiretrovirals with proven efficacy is high but falling worldwide, making the introduction of life-saving antiretroviral treatment programs possible in many resource-limited settings. The search for effective low-cost

antiretroviral therapies must continue and be intensified in all countries.

As with other antibiotics, low or intermittent dosing with antiretrovirals as a cost-saving measure is to be discouraged because it has no therapeutic benefit and may lead to community spread of resistant virus. Short-term administration of antiretroviral drugs is warranted only for certain, clearly defined prophylactic indications, such as prevention of maternal-fetal transmission or prevention of needlestick infection in health care workers.

## Experimental Therapies

Experimental drug therapies in various stages of clinical development include integrase inhibitors, tat inhibitors, and zinc finger encapsulation inhibitors. A variety of gene therapy approaches, in which DNA is introduced into cells, are being explored, including transdominant mutant viral proteins that interfere with normal viral replication steps, or intracellular synthesis of antiviral antibodies that can bind to viral proteins.

"Vaccine therapy" trials have been conducted in which candidate vaccines are administered to infected patients in an attempt to improve the anti-HIV immune response through antigen-specific immunotherapy. Although new antibody and cellular immune responses to HIV proteins can be stimulated, there has been no clinical benefit.<sup>266</sup>

Cytokines can also be used to treat HIV-infected patients. The first cytokine use was gamma interferon (IFN- $\gamma$ ). Although the antiretroviral effects of parenterally administered IFN- $\gamma$  are modest, the effects on Kaposi's sarcoma were sufficiently striking that the drug was approved for this specific indication.<sup>266,267</sup> The mechanism of action is uncertain. Initial reports of encouraging results with oral low-dose IFN- $\gamma$  were not confirmed by the findings of controlled trials sponsored by WHO.

Interleukin-2 (IL-2), a cytokine that stimulates proliferation of lymphocytes, has been shown in clinical trials to produce a marked increase in circulating CD4+ cell counts.<sup>268</sup> Fears that IL-2 treatment would increase in vivo HIV replication rates have not been realized. Controlled trials are under way to determine whether the rise in CD4+ cell counts provoked by IL-2 therapy has therapeutic benefit proportional to the rise in cell count. Finally, malabsorption of antiretroviral drugs may be a problem in patients with diarrhea or enteric infections, and new approaches for treating such patients are under study.<sup>269</sup>

## Specific Antiretroviral Recommendations: Who, When, and How

Rapid advances in HIV/AIDS research continue to modify and refine the guidelines for whom to treat, when during the course of infection treatment should be begun, and which therapeutic regimen should be used. Recent recommendations are presented here.<sup>270</sup>

- Who? The International AIDS Society–USA panel recommends therapy for any patient with established HIV infection who is committed to the complex, long-term therapy.
- When? Therapy is usually begun when the CD4+ cell count drops below 200 cells/ $\mu$ L (with consideration at higher

CD4+ levels and symptomatic disease) or when the plasma HIV-1 RNA level is greater than 100,000 copies/mL.

- How? Initial therapy should be with a combination of antiretroviral drugs, usually a minimum of three drugs. Nucleoside or nucleotide reverse transcriptase inhibitors (AZT, DDI, DDC, d4T, 3TC, fenovir, FTC) are used in combination with NNRTIs (nevirapine, efavirenz) and/or protease inhibitors (ritonavir, indinavir, nelfinavir, saquinavir, lopinavir/ritonavir).

As new results become available, these recommendations will be modified.

## Drug Resistance

HIV rapidly develops resistance to antiretroviral drugs in vivo. Drug-resistant variants have been found in blood after monotherapy with every antiretroviral thus far evaluated.<sup>271,272</sup> Emergence of resistance does not require patient exposure to an exogenous source of resistant virus; mutation and natural selection can evolve a population of resistant viruses within a single patient in a matter of weeks or months. Resistant HIV can be subsequently transmitted to uninfected persons. Resistance to an antiviral drug is typically generated through mutations affecting amino acids in the HIV target enzyme that are near the drug active site. Many different mutations can lead to resistance to a single drug, and these different mutations are often synergistic in conferring resistance.

Two biochemical mechanisms abrogate the incorporation of triphosphorylated NRTIs, thus leading to drug resistance. The first mechanism is mediated by a mutation that allows reverse transcriptase to discriminate against NRTI during DNA synthesis, as a result preventing their addition to the primer DNA chain. The second mechanism is mediated by mutations in the enzyme that increase the rate of hydrolytic removal of the chain terminating NRTI and to enable the continuous synthesis of viral DNA.<sup>273,274</sup> The NNRTIs, which bind to a hydrophobic pocket in reverse transcriptase, close to, but not contiguous with, the active site, inhibit HIV-1 replication allosterically by displacing the catalytic aspartate residues relative to the polymerase binding site. A single mutation in the hydrophobic pocket can result in high-level resistance to one or more NNRTIs. Resistance to NNRTIs appear to emerge by the selection of a pre-existing population of mutant viruses in an individual. This is linked to the fact that resistance rapidly develops when NNRTIs are administered as monotherapy or in the presence of incomplete virus suppression. Resistance to PIs is mediated by structural changes that reduce binding affinity between the inhibitor and the mutant protease molecule. Resistance to protease has also been attributed to mutations at the cleavage sites.<sup>275–277</sup> Mutations occurring outside the active site appear to induce resistance by other mechanisms such as alterations in enzyme catalysis, effects on dimer stability, alterations in inhibitor binding kinetics, or active site reshaping through extensive structural disturbances.<sup>278,279</sup>

In any given patient, the rapidity with which resistance emerges is directly related to the viral replication rate: a high replication rate generates mutants at a high rate. Combination therapies of two or three antiretroviral drugs with different mechanisms of action may lower the replication rate sufficiently to retard the breakthrough of drug-resistant variants.

Although this has yet to be proved, early results are encouraging. Recent reports that combinations of antiretrovirals can sterilize blood and perhaps lymphoid tissue of detectable virus have raised hopes that HIV infection may not just be treatable but curable. Studies are under way to determine whether long-term combination chemotherapy of HIV can lead to cure just as long-term combination chemotherapy of MTB can lead to cure of tuberculosis.

Drug resistance can be monitored at three levels: clinical, phenotypic, and genotypic. Clinical unresponsiveness to therapy suggests resistance. For example, a rapid fall in the CD4+ count with a rise in the plasma HIV RNA level strongly suggests emergence of resistance in a treated patient. This can be verified by virus isolation followed by drug sensitivity testing in virus-infected cell cultures, but this process is complicated and expensive. For those drugs where the principal resistance mutations are well characterized, PCR amplification and screening of the viral genome can detect common mutation patterns.

### Prevention of Opportunistic Infections and Cancers

Prevention of opportunistic infections (OIs) in HIV-infected patients can be accomplished in three ways: (1) preventing exposure to pathogens in the environment, (2) preventing an initial episode of disease through chemoprophylaxis or vaccination, and (3) preventing disease recurrence through chemoprophylaxis. Opportunistic cancers can be prevented by screening and treatment of precancerous lesions.

Prevention of exposure to opportunistic pathogens requires knowledge of their environmental sources. For many common OIs, e.g., PCP, the exact environmental sources are still uncertain. In some, such as *P. marneffei* infection, the sources (thought to be moldy sugar cane or bamboo) are unique to certain geographic regions.<sup>280</sup> Some universal practical measures include avoidance of contact with known tuberculous patients in health care facilities; avoidance of raw or uncooked eggs, poultry, or dairy products that might harbor *Salmonella*; and avoidance of undercooked meat that may be a source of *Toxoplasma*. Some water-borne OIs, such as intestinal parasites and possibly MAI, may be difficult to avoid, but where possible only clean water sources should be used.

Chemoprophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) with one double-strength tablet daily has been proved to reduce the occurrence of PCP and to prolong survival in HIV-infected patients in North America.<sup>281</sup> In South America and Asia, where PCP appears to be a common OI, daily TMP-SMX prophylaxis is recommended for patients with advanced infection. Recent studies from Uganda and Zambia in HIV-infected adults and children, respectively, have shown a marked reduction in morbidity and mortality following the introduction of TMP-SMX.<sup>282,283</sup> The incidence of other OIs is also reduced, including cerebral toxoplasmosis and some bacterial infections.<sup>284</sup> Daily TMP-SMX costs about U.S. \$60 per year.

Chemoprophylaxis with isoniazid (INH) has been proved to prevent clinical tuberculosis in HIV-infected persons.<sup>285</sup> Ideally, prophylaxis should be used in HIV-infected persons who are shown to be tuberculin skin test-positive but without active tuberculosis. However, the reality in many developing countries is that many HIV-infected patients are already anergic at the time of diagnosis. Furthermore, in many countries skin

test reactivity may reflect childhood bacille Calmette-Guérin (BCG) immunization. Consequently, some have suggested that in regions where MTB prevalence is high, INH prophylaxis should be considered for all HIV-infected patients who do not have active tuberculosis.<sup>286</sup> WHO and the International Union Against Tuberculosis recommend that prophylaxis be given for 6 to 12 months. This costs about U.S. \$60 per year. Several studies of prophylaxis against tuberculosis are currently under way in Africa and Asia.

Bacterial infections, particularly *Streptococcus pneumoniae*, are an important cause of morbidity and mortality among HIV-infected patients in developing countries. The polyvalent pneumococcal vaccine costs U.S. \$10 and should be considered.

Human papillomaviruses play an etiologic role in cervical cancers in women and penile and anal cancers in men. Routine screening of HIV-infected patients for perineal and genital dysplasias and precancers with treatment of early lesions is suggested.

### Treatment of Opportunistic Infections

Management of the clinically ill, late-stage HIV patient is difficult in any setting, but it is particularly challenging in developing countries where diagnostic and therapeutic options are limited. Experienced physicians often use syndrome-based diagnoses to choose therapies from locally available alternatives. The approach to patients with tropical infectious disease complications of HIV infection is presented in Chapter 133.

### Counseling of Patients and Families

A diagnosis of HIV/AIDS can be a devastating psychological blow. In all societies, patients require ongoing emotional support and access to factual, up-to-date information. This can be provided by medical professionals or, alternatively, by trained paraprofessionals or volunteers. Information about prognosis and treatment options is the most obvious need. However, HIV-infected patients usually need assistance with a variety of important life decisions: whom to inform about their illness; how to avoid transmitting infection to others; childbearing options; coping strategies; and custody and death planning, to name a few.

### PREVENTION AND CONTROL

HIV prevention efforts can focus either on reducing transmission from already infected patients or on reducing risk in uninfected persons.

### HIV Testing as a Public Health Tool

One approach to HIV epidemic control is test-linked interventions: HIV testing coupled with efforts to reduce transmission by those found to be infected.<sup>287–289</sup> This approach reflects the traditional public health philosophy of communicable disease control. During the 1980s a vigorous international debate ensued over the potential benefits of HIV testing, reporting, contact tracing, and quarantine versus the negative impact of such steps on human rights. When aggressive HIV testing systems were implemented in several countries, WHO became concerned about the threat of

stigmatization and discrimination and led a laudable international movement to ensure that nondiscrimination was an integral part of global HIV/AIDS control. WHO also condemned mandatory HIV control programs and put a low priority on testing and counseling. The WHO campaign to minimize discrimination appears to have been successful. Public health programs in which HIV testing is linked to treatment and behavioral counseling to reduce transmitting behaviors should also be considered to slow the global spread of HIV.

In at least one specific setting, test-linked interventions to reduce transmission do have near-universal support. This is in maternal-infant transmission. Chemoprophylaxis with AZT around the time of delivery is proved to substantially reduce the risk of maternal-to-infant transmission. Pregnant women are advised to be HIV-tested, and there have been calls for mandatory testing in this setting.

Among certain groups of at-risk adults, test-linked interventions may be the only practical way to prevent infection. For example, the common public health recommendation to limit the number of sexual partners is irrelevant advice for a monogamous spouse, although use of condoms may not be. In high-incidence regions where infection of males by commercial sex workers is common, the only way a monogamous married woman may reduce her own risk is to find out if her husband is infected and make difficult—but informed—choices.

Although the ethical issues are complex, test-linked public health programs can be considered if the following conditions apply: (1) testing is accurate, (2) medical treatment is available, (3) legal rights are secure, and (4) cost-benefit calculations are favorable.

### Behavioral Prevention in At-Risk Populations

Public health efforts to change human behavior are never simple.<sup>290</sup> In the words of a highly regarded Ugandan HIV training video, “it’s not easy.” Health education—conveying a knowledge of the facts—is just one step toward behavior change.<sup>291</sup> The full sequence of steps to reach behavior change is often abbreviated as KABP—for knowledge, attitude, belief, and practice. Many persons become HIV-infected even though they have substantial knowledge about what HIV is, how it is transmitted, and how it can be prevented. A receptive attitude is crucial. Unless the subject believes that this is an issue of personal importance and that the changes can be of personal value and is willing to put into practice risk-avoidance skills, then knowledge alone is insufficient.

Behavioral interventions intended to prevent sexually transmitted HIV infections can be designed to reach one at-risk person at a time, small groups of at-risk persons, or larger community or societal groups. Interventions targeted at individuals or small groups permit focusing of resources to those most at risk and minimize political reaction by restricting discussions of sensitive issues and avoiding public forums. However, they are highly personnel-intensive and expensive. Individual counseling has been recommended for persons who seek HIV testing. Community- and societal-level interventions through mass media can be highly effective in reaching many people at once, but the heterogeneity of risks in large groups means that only the most basic messages enjoy widespread public acceptance. Public discussions of “safe sex” have been vigorously opposed in some quarters.

Efforts to control HIV in populations of injection drug users have reconfirmed the lesson that knowledge-only programs are not very effective in bringing about long-term behavior change. Changes in attitudes and beliefs typically require a social change process, so newer control efforts have targeted the social settings for drug use.<sup>292</sup> Peer influence is an important factor in social change, and two-way programs that involve current drug users are more effective than one-way, top-down policies. Providing the means for safe injection practices is another proven control method. Data from several countries suggest that over-the-counter sale of needles and syringes reduces the use of contaminated injection “works,” and reduces HIV transmission. However, this approach has encountered intense political resistance.

### Progress Toward an HIV Vaccine

There is no HIV vaccine with proven protective efficacy. Given the current state of progress and level of effort, a globally available and affordable HIV vaccine is at least a decade away. More than two dozen HIV candidate vaccines have been tested in phase I clinical trials in humans, primarily in the United States and Europe. However, only two of these have been carried forward to phase II trials, and there are currently no plans anywhere in the world for large-scale phase III efficacy trials.<sup>293</sup> Some of the scientific, political, and economic obstacles to global HIV vaccine development are reviewed here.<sup>294</sup>

#### Scientific Obstacles

The key unsolved scientific problem in HIV vaccine research is the mechanism of immunity. Although vaccine-induced protection has been demonstrated in SIV analog vaccine models, there is uncertainty whether protection is primarily humoral or cellular and which epitopes are crucial. A parallel problem is how to measure correlates of immunity in vaccine trials. For example, many candidate vaccines induce HIV-neutralizing antibodies but only against selected laboratory-adapted viruses, not against fresh “street virus” isolates.

#### Political Obstacles

Most incident HIV infections today occur in developing countries, where the prevalent HIV strains differ from those in candidate vaccines. Regrettably, there has been no coordinated international effort to produce candidate vaccines that would be suitable for testing in developing countries. Furthermore, vaccine testing capabilities in many regions are still suboptimal despite serious efforts by WHO to strengthen research infrastructures. Concern about exploitation (the “guinea-pig issue”) is one example of a host of important political issues that must be overcome.

#### Economic Obstacles

Vaccines in general are not a highly profitable venture for industry, especially compared to therapeutics. Liability is an ever-present threat. Other economic disincentives that are unique to private-sector HIV vaccine research and development include the following: vaccine demand is greatest in populations least able to pay; different vaccine types may be

necessary for developing countries; and calls for “distributive justice” by activists may force price ceilings.

With global cooperation, none of these obstacles is insurmountable. A new effort under the sponsorship of the Rockefeller Foundation called the International AIDS Vaccine Initiative has begun to build global partnerships that directly involve all parties: scientists, manufacturers, at-risk populations, developing and industrialized countries, and international organizations.

## TURNING THE TIDE ON THE AIDS PANDEMIC

The provision of antiretroviral (ARV) therapy treatment for AIDS in resource limited settings has become a reality in recent years thanks to increases in donor support, political will, and a gradual reduction in the cost of antiretroviral drugs. Despite this optimism, only 7% of individuals needing ARVs in resource-limited settings were receiving treatment at the end of 2003.<sup>11</sup> (Fig. 76-10). Resource-limited countries affected by the AIDS pandemic face tremendous challenges to implement ARV programs that are sustainable and can meet the tremendous demands that will be placed on existing health-care institutions.

### Global HIV/AIDS Funding

The amount of global AIDS funding has increased 15-fold from U.S. \$300 million in 1996 to U.S. \$5 billion in 2003.<sup>11</sup> Unfortunately, the funding gap has grown substantially as more money is made available, and this amount represents roughly half of what will be required for resource-limited countries by 2005. Costing estimates for 2007 indicate that \$20 billion will be required for HIV prevention and care in low- and middle-income countries. This amount will not be met with current domestic and international development agendas and represents an enormous challenge to donor countries.

Several key milestones have occurred in response to the AIDS pandemic, making the possibility of ARV treatment a reality in resource-limited settings. The Global Fund to Fight

AIDS, Tuberculosis and Malaria (GFATM) was created to increase the global resources available to combat these major killers affecting developing countries. GFATM has now gone through four rounds of funding and more than \$1.6 billion has been allocated over 2 years for HIV/AIDS projects in 94 countries.<sup>295</sup> The GFATM money will allow for 700,000 individuals to receive life-saving ARV treatment through its various programs.<sup>11</sup> In the State of the Union address of January 2003, President George W. Bush announced an unprecedented 5-year, \$15-billion Emergency Plan for AIDS Relief (PEPFAR) to provide HIV care, prevention, and treatment in 15 countries severely affected by the HIV/AIDS pandemic.<sup>296</sup> Currently 15 countries supported through the PEPFAR program are implementing programs focused on ARV treatment, prevention of mother-to-child transmission (PMTCT), HIV prevention, and support for orphans and vulnerable children. The ambitious goal of this program is to treat 2 million people with ARVs, prevent 7 million infections, and care for 10 million HIV-infected individuals by 2007. WHO also has embarked on an ambitious plan to mobilize support for the treatment of 3 million HIV-infected individuals with ARVs by 2005 with a focus on urgency, equity, and sustainability. Support from the World Bank's Multi-country AIDS Program (MAP) is delivering \$1 billion to Africa for HIV care and \$155 million to the Caribbean. Increasing support from these agencies coupled with the growing private sector involvement has provided a platform for universal access to HIV care in many countries, a goal that was seemingly impossible only 5 years ago. Most countries worst hit by the HIV pandemic have now developed national AIDS plans incorporating ARV treatment and basic HIV care. Several countries in Latin America and the Caribbean now offer universal ARV coverage. Brazil was the first developing country to implement a universal HIV/AIDS treatment policy, and currently 141,000 patients receive ARVs free through the public health system. The Brazilian government estimates that from 1997 to 2003, more than 60,000 new AIDS cases, 90,000 deaths, and 633,200 AIDS-related hospital admissions have been avoided.<sup>297</sup> The overall cost savings from this program is estimated at U.S. \$200 million, not taking into account the social benefit of this program. The Brazilian experience has demonstrated that with government political will and the involvement of other key players in health delivery, it is possible to turn the tide on the AIDS pandemic.

**FIGURE 76-10** Percentage of the estimated 6 to 8 million HIV-infected patients who should be on antiretroviral therapy who are receiving antiretroviral drugs by 2004 by region. Only 400,000 had access to antiretroviral drugs, equaling coverage of only 7%. (Data from UNAIDS Program.)

### The Challenges Ahead

The complexity of HIV care warrants a dramatic effort to strengthen human capacity to deliver ARVs. Twenty antiretroviral drugs are now approved by the FDA for the treatment of HIV infection and have an array of potentially serious side effects and drug interactions.<sup>298</sup> Decisions about which drugs to start with, when to start, and when to change therapy have become increasingly complex as the number of available choices increases. The training demands imposed by the complexity of HIV treatment is magnified by the reality of the scarcity of health workers in many resource-limited settings. In many settings, the current health work force must triple or quadruple to achieve the ambitious goal of universal ARV coverage. In countries most affected by AIDS, vacancy rates remain high, Malawi for example has only been able to fill half of its public sector nursing posts in recent years.<sup>11</sup>

**Table 76-2** WHO Recommendations for Initiating Antiretroviral Therapy in Adults and Adolescents with Documented HIV Infection and Possible First-Line ARV Regimens

- WHO stage IV disease, irrespective of CD4
- WHO stage II disease, including but not restricted to HIV wasting, chronic diarrhea of unknown etiology, prolonged fever of unknown etiology, recurrent invasive bacterial infections, or recurrent/persistent mucosal candidiasis, with consideration of CD4 cell count  $<350/\text{mm}^3$  in decision-making
- WHO stage I or II disease with CD4 cell counts  $<200$

In settings where CD4 testing is unavailable:

- WHO stage III or IV disease irrespective of total lymphocyte count
- WHO stage II disease with total lymphocyte count  $<1200/\text{mm}^3$

ARV Regimen	Major Potential Toxicities	Usage in Women (of Childbearing Age or Pregnant)
D4T/3TC/NVP	D4T-related neuropathy, pancreatitis and lipoatrophy NVP-related hepatotoxicity and severe rash	Yes
AZT/3TC/NVP	AZT-related GI intolerance, anemia, and neutropenia NVP-related hepatotoxicity and severe rash	Yes
D4T/3TC/EFV	D4T-related neuropathy, pancreatitis, and lipoatrophy EFV-related CNS toxicity and potential for teratogenicity	No*
AZT/3TC/EFV	AZT-related GI intolerance, anemia and neutropenia EFV-related CNS toxicity and potential for teratogenicity	No*

AZT, zidovudine; D4T, stavudine; EFV, efavirenz; NVP, nevirapine; 3TC, lamivudine.

\*For women in whom effective contraception can be assured, EFV remains a viable option.

From Scaling up antiretroviral therapy in resource-limited settings: Treatment guidelines for a public health approach. Available at [http://www.who.int/hiv/pub/prev\\_care/en/arvrevision2003en.pdf](http://www.who.int/hiv/pub/prev_care/en/arvrevision2003en.pdf). Accessed 12/01/05.

As countries expand HIV care programs to meet the current expanded access goals, training and recruitment of health sector workers will be necessary to provide the platform to build sustainable programs.

Current North American and European clinical care guidelines incorporate measurements of plasma HIV viral load and CD4+ T lymphocytes as essential tools in managing patients on HAART.<sup>298</sup> In addition, testing for viral resistance has become a key tool in managing patients with evidence of virologic failure on HAART. Many countries faced with the challenge of delivering ARVs in resource-limited settings lack the laboratory infrastructure and trained technicians to perform the routine chemistry and hematology assays necessary to monitor patients receiving HAART. The more sophisticated virologic tests that have become standard of care in the North

American and European settings remain prohibitively expensive for most countries developing HIV treatment programs. The WHO has responded to this challenge by publishing treatment guidelines aimed at resource limited settings (Table 76-2 and Box 76-2). Alternative, low-cost methods for monitoring patients receiving HAART have become a public health priority, but early results have failed to reveal a low-cost alternative that performs as well as the more expensive immunologic and virologic tests.<sup>299</sup>

The threat of antiretroviral resistance looms over the many countries scaling up ARV delivery programs. ARV resistance

### Box 76-2 World Health Organization Classification System for HIV Infection

#### Clinical Stage 1

1. Asymptomatic infection
  2. Persistent generalized lymphadenopathy
  3. Acute retroviral infection
- Performance stage 1: asymptomatic, normal activity level

#### Clinical Stage 2

4. Unintentional weight loss  $<10\%$  body weight
  5. Minor mucocutaneous manifestations (e.g., dermatitis, prurigo, fungal nail infections, angular cheilitis)
  6. Herpes zoster within previous 5 years
  7. Recurrent upper respiratory tract infections
- Performance stage 2: symptomatic but nearly fully ambulatory

#### Clinical Stage 3

8. Unintentional weight loss  $>10\%$  body weight
  9. Chronic diarrhea  $>1$  month
  10. Prolonged fever  $>1$  month (constant or intermittent)
  11. Oral candidiasis
  12. Oral hairy leukoplakia
  13. Pulmonary tuberculosis within the previous year
  14. Severe bacterial infections
  15. Vulvovaginal candidiasis
- Performance stage 3: in bed more than usual but  $<50\%$  of daytime during the previous month

#### Clinical Stage 4

16. HIV wasting syndrome
  17. *Pneumocystis carinii* pneumonia
  18. Toxoplasmosis of brain
  19. Cryptosporidiosis with diarrhea  $>1$  month
  20. Isosporiasis with diarrhea  $>1$  month
  21. Cryptococcosis, extrapulmonary
  22. Cytomegalovirus disease of an organ other than liver, spleen, or lymph node
  23. Herpes simplex virus infection, mucocutaneous
  24. Progressive multifocal leukoencephalopathy
  25. Any disseminated endemic mycosis (e.g., histoplasmosis)
  26. Candidiasis of the esophagus, trachea, bronchus, or lung
  27. Atypical mycobacteriosis, disseminated
  28. Non-typhoid *Salmonella* septicemia
  29. Extrapulmonary tuberculosis
  30. Lymphoma
  31. Kaposi's sarcoma
  32. HIV encephalopathy
- Performance stage 4: in bed  $>50\%$  of daytime during previous month

could be devastating to resource-limited countries, resulting in early treatment failure and potentially abrogating the effectiveness of zidovudine, lamivudine, and nevirapine for the prevention of mother-to-child transmission of HIV. Countries embarking on ARV treatment programs need to ensure sustainable drug supplies in order to avoid the early pitfalls seen in the Ivory Coast, Gabon, and Uganda, where erratic therapy resulted in high levels of drug resistance.<sup>300–302</sup> Effective adherence strategies combined with stable drug supply in resource-limited settings has been shown to result in high levels of viral suppression, which hopefully will avoid widespread development of ARV resistance.<sup>303</sup>

The current expansion of ARV delivery to some areas hardest hit by the HIV pandemic provides hope and optimism for the future. The experiences of Brazil, Haiti, Thailand, Uganda, Senegal, and South Africa provide a wealth of information to design high-quality HIV treatment programs to greatly improve the health of nations facing the current HIV pandemic.<sup>304–308</sup> We have learned about secondary benefits of these programs from the findings in South Africa that HAART reduced the incidence of tuberculosis associated with HIV by 80%.<sup>309</sup> It is clear from evidence from North America, Europe, and Australia that adherence to therapy is difficult, and suboptimal antiretroviral regimens that are not as effective as HAART may result in the rapid development of drug resistance. As access to HAART expands, it is imperative that programs be supported with the necessary infrastructure to ensure high levels of adherence to build on the success demonstrated in the early treatment programs.

Enthusiasm over the expansion of ARV treatment programs throughout resource-limited settings should not overshadow the importance of basic HIV care and HIV prevention. Basic care and prophylaxis for the prevention of opportunistic infections remain low-cost interventions having the potential to greatly reduce morbidity and mortality among HIV-infected individuals.<sup>283</sup> Efforts to provide access to HAART that do not incorporate other low-cost interventions into a primary care plan could limit the potential effect of these programs on reducing morbidity and mortality among HIV-infected patients in resource-limited settings. Finally, prevention methods must be emphasized as treatment programs expand, to limit the number of new HIV infections and avoid any potential risk disinhibition that could result from the introduction of HAART into communities.

# Dermatophytosis

MICHAEL B. SMITH  
MICHAEL R. MCGINNIS

## INTRODUCTION

*Dermatophytosis* is a term used to describe mycotic infections caused by a group of fungi that usually remain localized to the superficial layers of the skin, hair, or nails. This disease is one of the most common infectious maladies worldwide. Despite their propensity to infect the exterior aspects of the host, the dermatophytes prefer a warm, moist environment for growth. As these conditions are prevalent in the environment of the tropics, it is no surprise that dermatophyte infections, while occurring in all parts of the world, are especially common in tropical regions.<sup>1</sup> Dermatophyte infection of the skin and hair of the scalp (tinea capitis) is exceedingly common in Africa, with a prevalence of 14% to 86% in children, depending on geographic location and the method of making the diagnosis.<sup>1</sup> In many tropical regions, dermatophyte infection of the glabrous skin (tinea corporis) is the most common skin disease found.<sup>1</sup> The rate of infection for those not native to a tropical area is usually higher than that of the indigenous population and can reach epidemic proportions. Both United States combat forces in Vietnam during the 1960s and British forces several decades earlier in Malaysia and Hong Kong experienced epidemic rates of dermatophyte infections. In Vietnam, 73% of U.S. combat infantrymen suffered from dermatophyte infections.<sup>2</sup> These infections were disabling enough that the soldiers were unable to capably perform in the field, and the deleterious effect on U.S. combat capability was sufficient to warrant the creation of a special medical research team by the military to address the problem.<sup>2</sup>

## AGENTS

Dermatophytes are a closely related homogeneous clade of keratinophilic filamentous fungi<sup>3-6</sup> that are associated with the stratum corneum of the skin, as well as hair and nails on the living host. They possess similar appearance, physiology, antigenicity, growth requirements, infectivity, and pathology. These fungi are classified in the anamorphic genera *Epidermophyton*, *Keratinomyces*, *Microsporum*, and *Trichophyton*. Some dermatophytes may reproduce sexually when the opposite mating types are crossed with each other. The single

## G. FUNGAL INFECTIONS

ascomycete genus *Arthroderma* accommodates the known sexual forms of all of the dermatophytes.<sup>7</sup>

Even though the term *dermatophytosis* refers to an infection caused by a dermatophyte, not all dermatophytes may cause infection. The fungus colonizes the stratum corneum and then grows in a radial manner without penetrating viable tissue. Invasion of hair, which is nonliving tissue, is an example of colonization. If the fungus enters viable tissue and continues to grow, then infection is present. Majocchi's granuloma (a nodular perifolliculitis due to dermatophytes) and pseudomycetoma are examples of fungal invasion of viable tissue. Colonization or infection may result in disease if there is structural or functional harm. These may be evident as damaged or destroyed hair and nails, hyperhidrosis, pruritus, inflammation, or alopecia. Contamination, the presence of nonreplicating dermatophytes on keratinized tissue, does not occur.

In addition to dermatophytes, other species of fungi that do not colonize or invade the stratum corneum, hair, and nails on the living host are classified in the same anamorphic genera owing to their similar microscopic and colonial characteristics. Some of these species may break down keratin in substrates such as feathers and hooves, but these are no longer on the living host. These keratinophilic species are not dermatophytes. The term *dermatomycosis*<sup>8</sup> is parallel to dermatophytosis, but differs in that it encompasses colonization and infection of keratinized tissue by fungi not classified in the genera *Epidermophyton*, *Keratinomyces*, *Microsporum*, and *Trichophyton*. In addition, when their sexual forms are known, they are classified in genera other than *Arthroderma*.

## EPIDEMIOLOGY

Based on their principal ecologic niches, dermatophytes are categorized as either anthropophilic (people-loving), geophilic (soil-loving), or zoophilic (animal-loving). Several dermatophytes may be associated with more than one ecological niche. The major advantage of this classification scheme resides in determining the source of the dermatophyte causing an infection. Clinically, geophilic and zoophilic dermatophytes typically cause more severe, self-limiting lesions. In contrast, anthropophilic species cause lesions having little inflammation that persist for long periods of time.

Transmission of dermatophytes occurs through contact with hyphal fragments and arthroconidia, usually associated with skin scales or hair fragments deposited on fomites such as combs, towels, etc. Arthroconidia are airborne propagules that can easily disseminate from one host to another. They are formed by the fragmentation of hyphae. Animal studies have shown that arthroconidia are more infective for transmission than macro- and microconidia.<sup>9</sup> These propagules, whether airborne or associated with fomites, are probably the primary inoculum that causes new infections. Arthroconidia can remain viable for several years on skin scales or hair shed into the environment.<sup>10</sup>

There is variability with respect to geographical distribution of individual species (Table 77-1). Some species are

Table 77-1 Geographic Distribution of Selected Dermatophyte Species in the Tropics

found worldwide, while others are quite localized. The prevalence of an individual species in a given geographic location, and hence the disease it causes, is dependent on a number of factors including population migration patterns, lifestyle practices, primary host range, secondary host susceptibility, standard of living, and climatic preference.<sup>11,12</sup> Epidemiologic features of specific diseases are discussed in their respective sections.

DISEASES

Dermatophyte infections are clinically characterized by the body site that is involved. The term *tinea*, which is Latin for “larva” or “worm,” is used to refer to dermatophyte infections on the body. The ancient Romans associated skin lesions on humans with holes in wool blankets caused by the larvae of moths. The major clinical syndromes include tinea capitis, tinea corporis, tinea cruris, tinea pedis, and tinea unguium or onychomycosis.<sup>13–16</sup> The natural history of these clinical syndromes is similar.

Colonization begins in the stratum corneum. The outcome depends on the fungal strain and species, host, and anatomical site. For example, if glabrous skin is involved, the fungus grows radially to form distinctive circular lesions called ringworm (Fig. 77-1). Initially, the clinical appearance is patchy scaling or erythematous eruptions. As the fungus and host interact, inflammation of varying degrees occurs. If the etiologic agent is anthropophilic, the clinical symptoms may disappear, and the host typically becomes a healthy carrier.

Tinea Capitis

Tinea capitis is a worldwide, common disease, primarily of children, in which dermatophytes cause scaling of the stratum corneum, with or without inflammation (in most patients), and invasion of scalp hair follicles which subsequently results in alopecia. Tinea capitis is caused by species of either *Trichophyton* or *Microsporum*, with the most common etiologic agent varying geographically.<sup>12</sup> Initially, an erythematous papule develops, the fungus spreads laterally, and

FIGURE 77-1 Circular lesion of tinea corporis, commonly referred to as ringworm. (Courtesy of Edgar Smith, MD)

then enters hair follicles. During the anagen phase of the hair cycle, hairs are invaded and become grayish, discolored, and lusterless, hence the alternative term *gray patch ringworm*. Itching may become intense and alopecia results. Ulceration with kerion formation (a crusted, oozing lesion comprised of pus and keratin debris overlying granulation tissue) and scarring may develop.

The fungus grows into the hair bulb and forms hyphae in the cortex of the hair shaft. When the hyphae mature, they either form arthroconidia or decompose to form long channels. Ectothrix invasion is characterized by the presence of arthroconidia both within and around the hair shaft. This is easily recognized by the destruction of the hair cuticle. Endothrix invasion is characterized by the production of arthroconidia within the hair shaft with an intact hair cuticle. A special form of endothrix invasion, without the production of arthroconidia, is known as favus. The disease (favus means “honeycomb” in Latin) is characterized by yellow, crusted honeycomb-like masses (scutula) on the scalp, comprised of hyphae and keratin debris (Fig. 77-2). The hyphae within the hair cortex break down to form long channels. When these hairs are placed in a mounting fluid such as potassium hydroxide, air bubbles can be seen racing down the channels owing to capillary action. Favus is caused by *Trichophyton schoenleinii*, the prevalence of which has been declining in most areas of the world, although it remains an important pathogen both in Africa and Asia.

Ectothrix tinea capitis may be caused by anthropophilic, as well as geophilic and zoophilic, dermatophyte species. *Microsporum audouinii* once caused large epidemics in Europe and America prior to the use of griseofulvin. Once griseofulvin was used to treat infections caused by *M. audouinii*, the fungus declined markedly in frequency in developed nations.<sup>12</sup> Anthropophilic ectothrix tinea capitis is typically spread by child-to-child contact and resolves after several years when the infected telogen hairs are shed.

Ectothrix tinea capitis can be caused by geophilic and zoophilic species such as *M. canis* and *M. gypseum*. Kerion, keloid, and severe inflammation are more frequent than in infections caused by anthropophilic species. Zoophilic species like *T. mentagrophytes* var. *mentagrophytes* and *T. verrucosum* cause marked inflammation, often with suppurative folliculitis

**FIGURE 77-2** Scutula in a case of favus. (Courtesy of Libero Ajello, PhD)

**FIGURE 77-3** Tinea facialis caused by *T. verrucosum*, a zoophilic dermatophyte. (Courtesy of Libero Ajello, PhD)

(Fig. 77-3). Kerion formation and scarring with permanent alopecia is typical with resolution of the infection.

*Trichophyton tonsurans*, common in Europe, Russia, the Near East, Mexico, the United States, Puerto Rico, and northern South America, and *T. violaceum*, common in Central Asia, parts of Africa, and the Far East, are the major anthropophilic etiologic agents of endothrix tinea capitis (Fig. 77-4). Typically, these fungi tend to cause more severe infections than those caused by anthropophilic ectothrix agents. These two species cause “black-dot ringworm,” which is characterized by infected hairs that break off at the follicular orifice resulting in a “black-dot” on the scalp (Fig. 77-5). Unlike ectothrix tinea capitis, not all of the hairs within the area of endothrix tinea capitis are infected. For this reason, infected hairs must be selectively collected for microscopic examination and culture. Because they can be subsurface, a scalpel may be required to epilate the hair stubs for examination. The infection is chronic, often continuing into adult life. The host reaction is variable, for while inflammation is minimal in populations living in endemic areas, severe inflammation, kerion formation, scarring, and permanent alopecia can also occur, especially in American black children in whom the infection may be recalcitrant, relapsing, and difficult to treat.

**FIGURE 77-4** Tinea capitis caused by *T. tonsurans*. (Courtesy of Libero Ajello, PhD)

**FIGURE 77-5** Curled “black-dot hair” in endothrix tinea capitis. (Courtesy of Libero Ajello, PhD)

### Tinea Corporis

Tinea corporis results from colonization of the glabrous skin by a dermatophyte. The fungus grows principally in the stratum corneum and usually does not enter viable tissue. Scaling, with erythema, vesicles, and deep granulomas are typical. While species of *Trichophyton*, *Microsporum*, and *Epidermophyton* all can produce tinea corporis, *T. rubrum* and *T. mentagrophytes* are the most common etiologic agents.

Transfer of epithelial scales containing hyphae, arthroconidia, or a combination of both originating from an infected person or animal, or fomites such as clothing and furniture, or from an existing, sometimes subclinical lesion elsewhere on the patient's body, transmits the fungus to the skin of a susceptible person. The fungus enters the layers of cells composing the stratum corneum and spreads radially. After 1 to 3 weeks, clinical signs appear as the margin of the lesion expands. The fungus is eliminated from the central portion of the lesion, with concurrent formation of concentric zones of inflammation at the lesion's edge.

Tinea corporis exhibits two basic types of lesions: annular and vesicular. Anthropophilic dermatophytes such as *T. rubrum* and *E. floccosum* cause small, dry, scaly, spreading, annular

**FIGURE 77-6** Polycyclic rings of papulosquamous scales of tinea imbricata. (Courtesy of Carolyn Halde, PhD)

patches with elevated areas of inflammation and red margins. The central areas heal as the fungus spreads radially. The lesions may resolve or remain as a chronic problem.

The second type of lesion, vesicular, is similar to the annular lesion. Vesicles form behind the advancing elevated lesion margin with subsequent crust formation. Hair invasion results in pustules. The lesions typically resolve in a few weeks; chronic lesions are uncommon. Vesicular lesions are characteristic of zoophilic dermatophytes such as *T. mentagrophytes* var. *mentagrophytes* and *T. verrucosum*. Pustular, well-circumscribed, elevated, crusted lesions are known as Majocchi's granuloma. Secondary bacterial infection can result in severe inflammatory lesions that can be disabling.<sup>2</sup>

A special form of tinea corporis known as tinea imbricata is caused by *Trichophyton concentricum* in people living on the Pacific islands of Oceania, Southeast Asia, and Central and South America. The lesions consist of polycyclic rings of papulosquamous scales (Fig. 77-6) that can be scattered over as much as 70% of the body. It is believed that the fungus is transmitted by direct, intimate contact. Among the predisposing factors leading to infection is an autosomal recessive pattern of inheritance.<sup>17</sup>

### Tinea Cruris

Tinea cruris is an infection involving the groin, perineum, and perianal region that is prevalent in people living in tropical regions, where high humidity contributes to skin maceration. Both males and females may develop tinea cruris, but it is more common in males. Tinea cruris often occurs in conjunction with tinea pedis. The major pathogens are *T. rubrum* (the most common etiologic agent worldwide), *E. floccosum*, and *T. mentagrophytes*.

The initial lesion is circinate and becomes serpiginous. Lesions associated with *E. floccosum* develop distinct margins and raised borders with randomly dispersed vesicles or vesiculopustules containing serous exudate. The center of the lesion is brownish to red, with branny furfuraceous scales. In males, the infection typically begins on the thigh where it contacts the scrotum. A pruritic, erythematous rash develops with the infection extending downward on the inner thighs, often on the left side. The gluteal and pubic areas are often involved. If *T. rubrum* is the etiologic agent, it may extend to the waist, buttocks, and thighs. *T. mentagrophytes* infection may extend to the chest, back, legs, and feet. Acute infections are associated with intense itching.

Predisposing factors include diabetes, neurodermatitis, and friction between skin folds in obese people, perspiration, humidity, and irritants that contribute to skin maceration. The etiologic agent may originate from skin scales containing viable fungi, animal sources, and fomites. Epidemics usually involve people who are close to each other such as in barracks, dormitories, and locker rooms.

### Tinea Pedis

Tinea pedis is an infection of the feet caused by a dermatophyte. The interdigital spaces and soles are typically the sites of infection, with lesions varying from mild, chronic scaling to exfoliative, pustular, and bulbous. Tinea pedis occurs in 30% to 70% of the world's population, making it

**FIGURE 77-7** Chronic hyperkeratotic form of tinea pedis. (Courtesy of Libero Ajello, PhD)

the most common dermatophytosis. The absence of sebaceous glands and their fungistatic lipids in feet, residence in warm, humid climates, removal of protective surface lipids by sweating, and the wearing of shoes predispose feet to tinea pedis. Tinea pedis rarely occurs in populations that do not wear shoes.

Intertriginous-interdigital tinea pedis is the most common clinical form. The peeling, maceration, and fissuring of the skin with dead, white epidermis and debris, and frequent odor characterize this infection. Hyperhidrosis and exacerbation of the infection may result in the fungus spreading to the sole, heel arch, and dorsal surface of the foot. The infection is most severe during hot humid weather. *Staphylococcus aureus*, *Pseudomonas* spp., and other bacteria may co-infect, requiring the use of both antibacterial and antifungal therapy.

The chronic, papulosquamous, hyperkeratotic form is persistent. It tends to be bilateral with areas of pink skin and fine silver-white scales on a thickened red base (Fig. 77-7). When the lesions involve the entire foot, the term *moccasin foot* is used. Moccasin foot is frequent in patients who have atopic dermatitis. *Trichophyton rubrum* and *T. mentagrophytes* var. *interdigitale* are the principal agents of moccasin foot.

When zoophilic dermatophytes such as *T. mentagrophytes* var. *mentagrophytes* cause tinea pedis, a vesicular form of the disease develops. Vesicles, vesiculopustules, and occasional bullae occur in the intertriginous areas and spread to the dorsal foot, instep, and sometimes the heel and anterior areas. After rupturing, the vesicles have a distinctive ragged edge. The fungus can be seen growing in the inner surface of the vesicle roof. The infection can be incapacitating with cellulitis, lymphangitis, and lymphadenitis.

Dermatophytid (id) reactions, which are allergic manifestations at sites distant from the infected site, are associated with both tinea pedis and tinea capitis. The id reaction site consists of sterile groups of vesicles that are itchy and sometimes painful. Id reactions on the fingers and palms are associated with tinea pedis, whereas those on the trunk develop when patients have tinea capitis.

A fourth type of tinea pedis is an acute, ulcerative, and spreading eczematoïd vesiculopustular process complicated by secondary bacterial infections. The most common etiologic

agent is *T. mentagrophytes* var. *mentagrophytes*. Shedding of the entire surface of the sole has been described. An id reaction that is widespread is typically present.

### Tinea Unguium (Onychomycosis)

Tinea unguium occurs when a dermatophyte invades the nail unit. Strictly speaking, onychomycosis refers to invasion of the nail unit by nondermatophytic molds and yeasts; however, in common usage, *onychomycosis* is used to describe all fungal nail unit infections, regardless of their cause. Only dermatophyte involvement is considered here. Collectively, approximately 2% to 13% of the general population have nail unit invasion by fungi. Toenail infections are four times more common than infections involving fingernails. In temperate regions, *T. mentagrophytes* and *T. rubrum* cause over 80% of all nail unit infections. Pre-existing tinea pedis and trauma that weakens the union of the nail plate and nail bed allow the dermatophyte to penetrate the nail unit. Other factors such as aging (slower nail growth rate, increased trauma to the nail plate, decreased circulation, and foot size changes), heat and moisture, immunosuppression, and genetic predisposition have contributed to the increased occurrence of onychomycosis.

The most common form of onychomycosis is distal lateral subungual onychomycosis, which is commonly caused by *T. rubrum* and *T. mentagrophytes*.<sup>18</sup> The nail plate is yellow-brown with onycholysis and subungual hyperkeratosis. Superficial white onychomycosis occurs when a dermatophyte such as *T. mentagrophytes* invades the nail plate creating a white, crumbly appearance. This form of onychomycosis essentially involves toenails where the lesions coalesce to involve the entire nail surface. Nail dystrophy, invasion of the cornified layer of the nail bed, and hyponychium may occur. Proximal subungual onychomycosis (Fig. 77-8) was an uncommon entity until the era of human immunodeficiency virus (HIV) infections began. In a study of 62 acquired immunodeficiency syndrome (AIDS) patients, 54 (87%) had proximal subungual onychomycosis.<sup>19</sup> The fungus, usually *T. rubrum*, penetrates the proximal portion of the nail, which results in hyperkeratosis and onycholysis. A white hue extending distally under the proximal nail fold is characteristic.

**FIGURE 77-8** Proximal subungual onychomycosis and tinea pedis in an AIDS patient. (Courtesy of Raza Aly, PhD)

## Tinea Infections and AIDS

While early in the AIDS epidemic the prevalence of tinea infections did appear to be increased in this patient population, with the advent of improved antiretroviral therapy, this no longer appears to be the case. Approximately 20% of AIDS patients with CD4 counts less than or equal to 200/ $\mu$ l have either tinea pedis or onychomycosis, a rate not dissimilar to the immunocompetent population.<sup>20</sup> Although the number of tinea infections seen in AIDS patients approximates that seen in non-AIDS patients, the severity of infections and the variability of clinical presentation are increased.

Generalized infection can occur, often in patients with low CD4 counts, and while many times the disease is responsive to therapy, prolonged treatment, usually with oral therapy, is required, and in some cases the patients are unable to clear the infection.<sup>21,22</sup> Occasionally, infection with unusual species or infection by a species not commonly associated with a particular anatomic site, such as cases of *M. canis* tinea capitis or onychomycosis, is seen.<sup>22,23</sup>

Tissue invasion by dermatophytes in these patients is often sudden in onset, not necessarily associated with a hair follicle, encompasses larger areas, and extends deeper into tissue than with localized invasive lesions seen occasionally in immunocompetent persons (i.e., Majocchi's granuloma). Systemic invasion with a fatal outcome in AIDS patients has been reported, but appears to be infrequent.<sup>24</sup>

It should be noted that the medical literature addressing dermatophyte infections and AIDS originates primarily from the developed world, and that reports and studies addressing this subject in developing nations, where the AIDS epidemic is ravaging the population, and where tinea infections are common, are lacking.

## PATHOGENESIS AND IMMUNITY

Dermatophyte infection is initiated by adherence of arthroconidia to corneocytes, with a subsequent rapid germination and production of germ tubes (within 4–6 hours), which grow through layers of keratin in both a horizontal and vertical direction.<sup>10</sup> These pathogens are able to produce and secrete keratinases, lipases, proteases, and phosphatases, all of which aid the spread of the developing hyphae through the keratin layer.

Host resistance is a combination of nonspecific, innate immune mechanisms and an acquired immune response. The intact keratin layer inhibits penetration into deeper layers of the epidermis, at least initially, and allows exposure of the fungus to lethal UV light in some anatomic locations. The skin surface has a low moisture content and a relatively high temperature, which are not ideal conditions for fungal proliferation. Transferrin in serum may compete with the fungus for iron. Cytokine production in keratinocytes is stimulated by dermatophytes, and the release of factors such as interleukin-8 by keratinocytes results not only in an influx of neutrophils, but also stimulates increased proliferation of epidermal cells and increased keratinization, which encourages shedding of the fungi.<sup>25</sup> Dermatophytes have been shown to activate complement, with a resultant release of chemotactic factors.<sup>25</sup> Unsaturated fatty acids and lipids present in adult sebum are fungistatic and may serve as a primary resistance mechanism

against dermatophytes.<sup>26</sup> This may explain, in part, the resolution of many cases of dermatophytosis at puberty when the composition of lipids in sebum changes.

Dermatophytes are not, however, without their own defense mechanisms. The rapid germination time of these fungi makes elimination by rapid epidermal turnover less effective. Some species of dermatophytes can destroy complement-derived chemotactic factors.<sup>25</sup> Mannan, a cell-wall glycoprotein of fungi, not only inhibits the proliferation of keratinocytes, but, most importantly, has been demonstrated to inhibit the development of cell-mediated immunity against the infecting dermatophyte.<sup>20</sup> While antibody classes directed against different antigens present in dermatophytes occur in all infected patients, they are not thought to play any role in clearing an infection, and development of cell-mediated immunity appears to be the most important host factor in clearing an infection.

Infected individuals who are able to produce a decisive delayed-type hypersensitivity are able to clear their infections. The clinical course of a dermatophyte infection is related, at least in part, to the relative proportions of CD4 (T-helper) lymphocytes and CD8 (T-suppressor) lymphocytes generated in the immune response. Those patients who have decreased CD4 lymphocytes relative to CD8 lymphocytes tend to develop chronic dermatophyte infections.<sup>10</sup> Because 10% to 20% of the "immunocompetent" world population are thought to have chronic dermatophytosis, a selective cell-mediated immunodeficiency to dermatophytes in the population appears to be relatively common. The exact nature of this immunodeficiency and whether it is innate or acquired is yet to be completely described.

## DIAGNOSIS

The clinical differential diagnosis is extensive.<sup>13</sup> Tinea capitis must be distinguished from seborrheic dermatitis, psoriasis, lupus erythematosus, lupus vulgaris, alopecia areata, pseudopelade, impetigo, trichotillomania, staphylococcal pyoderma, folliculitis decalvans, and secondary syphilis. Tinea corporis may be confused with psoriasis, pityriasis rosea, nummular eczema, granuloma annulare, annular secondary syphilis, lichen planus, seborrheic dermatitis, discoid lupus erythematosus, fixed drug eruption, pityriasis versicolor, candidiasis, and erythema annulare. Tinea cruris must be differentiated from candidiasis, erythrasma, seborrheic dermatitis, psoriasis, lichen planus chronicus, and contact dermatitis; and onychomycosis can be confused with various nail abnormalities such as nonmycotic leukonychia, clubbing, Beau's lines, pachyonychia congenita, contact irritants, and other skin diseases that cause dystrophic nails. In clinical material, dermatophytes must be distinguished from other filamentous hyaline hyphae formed by *Aspergillus*, *Scopulariopsis*, *Fusarium*, and *Scytalidium* species. Isolation of the fungus is the only accurate way to identify the etiologic agent.

The diagnosis of dermatophytosis is based on the clinical presentation and the demonstration of hyaline, septate, branching hyphae in the stratum corneum, nail, or hair. The demonstration of dermatophyte hyphae in clinical specimens is accomplished by mounting the material in 10% to 20% potassium hydroxide, allowing the specimen to become clear, and observing the hyphae with a microscope. The production

of blue-green fluorescence when lesions are exposed to UV light with a Wood's lamp indicates the presence of *Microsporum* species.

The identification of dermatophytes is based on their colonial characteristics when grown on Sabouraud glucose agar, microscopic structures, temperature ranges for growth, a few limited nutritional tests, and their resistance to cycloheximide. Conidia and their anatomy are the principal microscopic structures used to speciate dermatophytes.<sup>27</sup> Even though DNA probes and polymerase chain reaction (PCR) have been developed, they are not currently a practical method of identifying dermatophyte species in the clinical laboratory.<sup>28</sup>

There are no distinctive histopathologic changes associated with dermatophytes. The fungi are hyaline and form hyphae that may have associated arthroconidia. The epidermis may appear unaffected to mildly hyperkeratotic with patchy parakeratosis. Acute lesions may be spongiotic, whereas inflammatory lesions contain accumulating neutrophils in microabscesses accompanied by hyperkeratosis. A mild to intense perivascular infiltrate with lymphocytes and plasma cells may be present in the dermis. In tinea capitis, the hair follicle contains large numbers of neutrophils. The fungus does not grow below the keratinizing zone of the hair. Spongiosis, dermal abscesses, and colonized hair shafts result in severely inflamed kerions.

## TREATMENT

Topical antifungal drugs are the most commonly recommended treatment for most dermatophytosis, excluding tinea capitis and onychomycosis, although oral agents are often necessary in difficult cases. The major compounds include the imidazoles, triazoles, morpholines, and allylamines.

The imidazoles (clotrimazole, econazole, ketoconazole, and miconazole) and triazoles (fluconazole, itraconazole) inhibit the ergosterol biosynthetic pathway by binding to the fungal cytochrome P-450–dependent 14 $\alpha$ -demethylase, which results in the accumulation of lanosterol and toxic metabolites in the fungal cell. Morpholines (amorolfine) result in the formation of ignosterol rather than ergosterol, which is required in the fungal plasma membrane. Allylamines (naftifine and terbinafine) inhibit squalene epoxidase, which transforms squalene to squalene epoxide, which is needed to form lanosterol and subsequently ergosterol.

Tinea capitis must be treated with oral antifungals because topical agents are unable to penetrate the hair shaft. Griseofulvin, because of its efficacy, safety, and low cost, is still considered by many to be the drug of choice.<sup>29</sup> The long course of treatment (8–12 weeks) required is a disadvantage, particularly where compliance is a concern. Additionally, increased doses over those required several decades ago are now necessary, and dose and duration of therapy are also dependent on species of the infecting dermatophyte, with *M. canis* requiring more therapy than *T. tonsurans*.<sup>30</sup> Cure rates with this drug are 70% to 100%. Pulse therapy, with periods of treatment alternating with periods of no treatment, have been used to address issues related to cost, compliance, and side effects.<sup>30</sup> Terbinafine is considered the second choice, except if the infection is caused by *M. canis*, for which it appears relatively ineffective (although it appears to be more effective for *T. tonsurans* than griseofulvin).<sup>29,30</sup> Itraconazole is efficient but expensive,

and ketoconazole does not appear to be useful compared to other options.<sup>29</sup> Adjuvant topical therapy with either 2% ketoconazole or 1% selenium sulfide shampoo is recommended to reduce infectivity.<sup>29</sup>

Griseofulvin is relatively poor in eradicating onychomycosis with only a 50% cure rate after 12 months of therapy.<sup>31</sup> Terbinafine, itraconazole, and fluconazole have all shown utility, although long-term follow-up has suggested that terbinafine may be superior in preventing relapse and that cure with fluconazole may not occur until up to one year after completion of therapy.<sup>31</sup> Chemical, surgical, or laser ablation of the nail may be necessary in addition to antifungal therapy.

For tinea cruris, tinea corporis, and tinea pedis, topical antifungals for 1 to 6 weeks are usually curative. Patients with the moccasin foot form of tinea pedis, widespread disease, disease that does not respond to topical therapy, or recurrent disease require oral therapy. There have been many clinical trials that have evaluated the comparative effectiveness of allylamines and azoles, with the allylamines overall appearing more effective, and with no detectable difference between individual allylamines or azoles.<sup>32</sup>

Treatment of dermatophytosis in the setting of AIDS is made more difficult not only by the problem of treating a patient that is severely immunocompromised, but also by the frequency of drug interactions between antifungals and the other medications these patients must take. For example, some of the azoles interact with protease inhibitors.<sup>20</sup> Antilipemics, necessary in conjunction with protease inhibitor therapy, preclude the use of itraconazole.<sup>20</sup> Finally, some aspects of the AIDS syndrome itself can interfere with effective therapy. Oral itraconazole, which requires an acidic environment for maximal absorption, may not achieve therapeutic serum levels at normal dosage due to the hypochlorhydria found in advanced AIDS.<sup>20</sup> Oral terbinafine appears to be helpful in many cases and is associated with fewer side effects than many other antifungals in this setting.<sup>20</sup>

## PREVENTION AND CONTROL

Prevention of tinea capitis requires good hygiene because most etiologic agents are anthropophilic dermatophytes. These are easily transmitted from one person to another. Tinea corporis prevention depends upon whether the dermatophyte is anthropophilic or zoophilic. When anthropophilic species are involved, clothing, towels, and bedding should not be shared. The animal source of zoophilic fungi such as *M. canis* needs to be located and treated. Tinea cruris often has a high recurrence rate. The groin area should be dried with a towel, using an absorbent powder to remove excess moisture and avoiding the use of occlusive garments. Tinea pedis relapse is very common. Antifungal powder placed on the feet and inside socks and shoes may be helpful. Daily bathing of feet and careful drying of the interdigital spaces, avoiding occlusive footwear, and not going barefoot in public facilities are appropriate preventive measures. Other than the use of antifungal lacquers, onychomycosis is difficult to prevent.

Effective vaccines against dermatophytes have been developed and used in the cattle industry.<sup>33</sup> LTF-130, a live vaccine against *T. verrucosum*, has been used successfully to reduce infections in cattle herds in Europe.<sup>34</sup> Immunity appears to be dermatophyte species-specific, and live attenuated vaccines

appear necessary, as an inactivated vaccine against *M. canis* studied in cats did not prevent disease.<sup>35</sup> No effective vaccines for dermatophytes are currently available for humans.

# Mycetoma

EL-SHEIKH MAHGOUB

## INTRODUCTION

Mycetoma is a subcutaneous, firm, commonly painless swelling, often characterized by the appearance of sinuses through which extrude grains or granules that are aggregations of the causative organism.<sup>1</sup>

These clinical symptoms are caused by an array of diverse microorganisms that have been placed into two groups: (1) aerobic actinomycetes, which are higher filamentous bacteria, and (2) true fungi. Mycetoma caused by the former is called *actinomycetoma* and that caused by the latter, *eumycetoma* (or *maduromycetoma*).

To differentiate between these two types is crucial for deciding on the line of treatment. A common mistake is to give the antibiotic treatment of actinomycetoma to patients with eumycetoma, or vice versa, simply because of their clinical similarities. Presumptive identification of the type of mycetoma can be established from the clinical picture, radiologic appearance of cavities in bones, color, and consistency of grains.

Mycetoma is a relatively frequent tropical fungal infection,<sup>2,3</sup> now being imported to northern countries by immigration and worldwide travel.<sup>4,5</sup> The causal agents of eumycetoma and their morphologic characteristics are shown in Table 78-1 and those of actinomycetoma in Table 78-2.

Mycetoma agents are soil saprophytes.<sup>6,7</sup> They gain entry into human tissue through a thorn prick, wood splinter, or stone cut.

**Table 78-1 Morphologic Characteristics of Grains of Organisms Causing Eumycetoma**

Organism	Color	Consistency
<i>Madurella mycetomatis</i>	Black	Hard
<i>Madurella grisea</i>	Black	Hard
<i>Leptosphaeria senegalensis</i>	Black	Hard
<i>Exophiala jeanselmei</i>	Black	Hard
<i>Pyrenochaeta romeroi</i>	Black	Hard
<i>Curvularia</i> spp.	Black	Hard
<i>Phialophora verrucosa</i>	Black	Hard
<i>Acremonium</i> spp.	White or yellowish	Soft
<i>Aspergillus flavus</i>	White or yellowish	Soft
<i>Aspergillus nidulans</i>	White or yellowish	Soft
<i>Fusarium</i> spp.	White or yellowish	Soft
<i>Neotestudina rosatii</i>	White or yellowish	Soft
<i>Pseudoallescheria boydii</i>	White or yellowish	Soft

**Table 78-2 Characteristics of Grains Containing the Agents of Actinomycetoma**

Organism	Color	Size
<i>Actinomadura madurae</i>	White	Large
<i>Actinomadura pelletieri</i>	Red	Small
<i>Nocardia asteroides</i>	Beige or orange	Minute
<i>Nocardia brasiliensis</i>	Beige or orange	Minute
<i>Nocardia transvalensis</i>	Beige or orange	Minute
<i>Streptomyces somaliensis</i>	Yellow	Small

## EPIDEMIOLOGY

Mycetoma is endemic in tropical and subtropical parts of the world. Most mycetomas in South and Central America are caused by *Nocardia* spp. and *Madurella grisea*; in the United States and Europe, by *Pseudallescheria boydii*, *Scedosporium apiospermum*,<sup>8</sup> and *Cephalosporium* spp.; in West Africa, by *Leptosphaeria senegalensis*; and in East Africa, by *Streptomyces somaliensis*. However, *Madurella mycetomatis* is found worldwide. Distribution of mycetoma cases is influenced by rainfall. In dry parts of the tropics where there are about 3 months of rainfall and a long dry season, *M. mycetomatis*, *S. somaliensis*, and *Actinomadura madurae* are encountered, while in wet parts with a much longer rainy season, *Nocardia* spp. and *Actinomadura pelletieri* are found.<sup>1</sup>

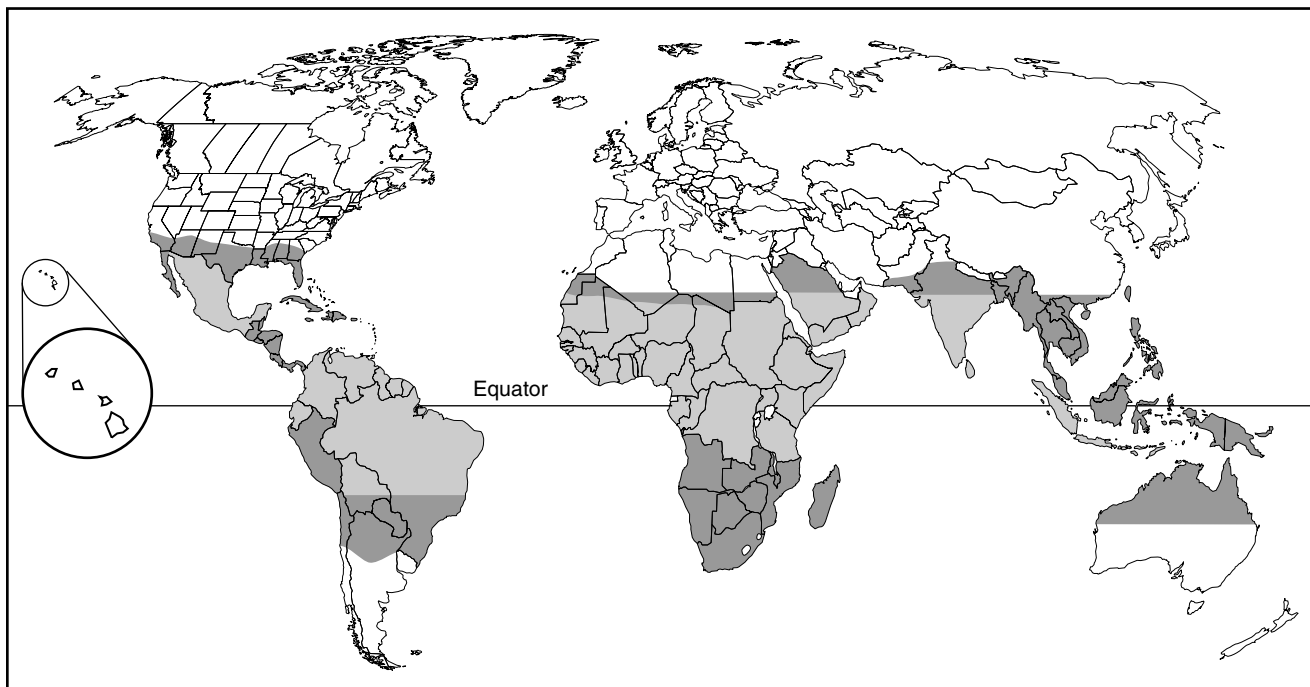

Mycetoma is primarily a human infection, though natural infection in animals has been reported.<sup>9</sup> The infection cycle, however, is always from soil to humans. Mycetoma patients are usually young adults between 20 and 40 years of age and male more than female in a ratio of 5:1. This ratio is reported from many countries and is not merely due to outdoor activities of men.

## DISEASE

The first lesion that the patient notices is a painless nodule the size of a peanut that slowly increases in size. In one fifth of cases, pain is the main complaint for which the patient seeks medical advice. As the mycetoma progresses, sinuses open, discharging pus and grains or granules the color and consistency of which depend on the causal organism (see Tables 78-1 and 78-2). A sinus may close but will open in a neighboring site. The clinical triad of a well-developed mycetoma, therefore, is painless swelling, sinuses, and grains. On the other hand, small intact tumors without sinuses are seen in endemic areas.

The lower limb—in most cases starting on the sole of the foot (Fig. 78-1)—is involved in more than 75% of cases, the hand in about 10% to 12%, followed by the back and other parts of the body (Plate 78-1 and Fig. 78-2).

Infection with mycetoma starts in the skin and underlying subcutaneous tissue, followed by bone, which in some cases may be the only site of infection. Mycetoma does not seem to affect muscles, though granules have been found among muscle fibers during surgical operations. Similarly, neither tendons nor nerves are involved, which may explain the absence of pain in many cases. The lesion spreads to neighboring parts through fascial planes. No hematogenous spread has been reported, but lymphatic spread is noted in about 2% of cases.<sup>10</sup>

#### Mycetoma

■ Endemic mycetoma areas

■ Areas with few reported cases

Involvement of internal organs is usually an extension from a subcutaneous lesion, for example, cutaneo-pleuro-bronchial fistulae leading to expectoration of mycetoma grains.<sup>11</sup> In two cases of intraspinal mycetoma, the grains appeared within an artery neighboring the dorsal spine. This may be the first report of hematogenous spread of mycetoma.<sup>12</sup>

The skin is often sweaty over the mycetoma and appears smooth, shiny, punctated with old healed and new sinuses, fixed to the underlying tissue, and possibly hypo- or hyperpigmented. The swelling is firm, rarely nodular, well encapsulated, and mobile in eumycetoma but with ill-defined margins and merging with surrounding tissue in actinomycetoma. The regional lymph nodes (inguinal or axillary) are usually small and shotty except when they are invaded by the mycetoma agent; then

they become enlarged and firm or may even discharge pus and grains through sinuses.

#### PATHOGENESIS AND IMMUNITY

Immune mechanisms attempt to engulf and kill the infecting fungi or actinomycetes. Chemotactic factors attract polymorphonuclear leukocytes and multinucleated giant cells to the site of infection<sup>13</sup> but are ineffective because organisms continue to grow and transform to grains. The filaments forming these grains are cemented together by a hard substance in *Madurella* spp. and *S. somaliensis*.

Three types of inflammatory reaction to mycetoma agents have been identified.<sup>14</sup> In type I, neutrophils degranulate and

FIGURE 78-1 Mycetoma of the foot.

FIGURE 78-2 Mycetoma of the hand and wrist.

become adherent to the surface of the grain, causing disintegration of the grain matrix and destruction of hyphae. This binding of neutrophils to the grains is observed in the presence of immunoglobulins, which are seen on the surface. However, the presence of immunoglobulins may also be nonspecific and result from their exudation together with other plasma proteins. In the type II response, neutrophils are largely absent, and macrophages are observed engulfing fragmented grain material and dead neutrophils. In the type III response, there is a well-developed epithelioid granuloma with Langhans giant cells. Most probably this represents a delayed-type hypersensitivity reaction.

Early experiments to produce mycetoma in immunocompetent animals failed, but typical mycetoma lesions containing well-developed grains with a surrounding polymorphonuclear reaction are produced in athymic nude mice with deficient cell-mediated immunity (CMI).<sup>15</sup> More recently, both immunocompetent male mice and immunocompromised female mice were infected with *M. mycetomatis*.<sup>16</sup> Similarly, studies of mycetoma patients demonstrate some deficiency of CMI.<sup>17</sup> Their lymphocytes fail to transform to lymphoblasts when challenged with phytohemagglutinin. They also fail to react when sensitized and challenged by dinitrochlorobenzene. On the other hand, all types of immunoglobulins were produced in abundance, although they were not protective. Antigenic relationships between *M. mycetomatis* strains causing mycetoma in Sudanese patients showed that there was little genetic variation among them and that different manifestations of mycetoma are due to host factors rather than to the various strains.<sup>18</sup>

## DIAGNOSIS

In endemic areas any subcutaneous swelling is considered a mycetoma until proven otherwise. The differential diagnosis includes neurofibroma, Kaposi sarcoma, fibrolipoma, malignant melanoma, osteomyelitis, and osteogenic sarcoma.

The diagnostic feature of a mycetoma in a radiograph is the presence of cavities. These are usually large in eumycetoma and mycetoma caused by *A. madurae* and are small and multiple in actinomycetoma (Fig. 78-3). These cavities contain hard grains with cement substance binding together *M. mycetomatis* or *S. somaliensis*. Spontaneous fracture does

**FIGURE 78-3** Mycetoma. Radiograph of the foot. Note the bone change.

**FIGURE 78-4** Histopathologic section stained with H&E. Note mycetoma grains of *M. mycetomatis*.

not occur. Periosteal erosion due to invasion from outside is seen in metatarsal or metacarpal bones. Bony changes in the skull are sclerotic, with dense bone formation. However, osteoporosis frequently is seen in bones of the limbs owing to either pressure on the blood supply or disuse atrophy or both.

A presumptive diagnosis of mycetoma can be made on clinical grounds, but a definitive diagnosis can be made only by culture of the organism, histopathology, or serology.

Although grains extruded through sinuses could be cultured, a deep-seated biopsy is preferred for both culture and histopathologic studies because grains coming through sinuses are often contaminated with bacteria and may not be viable. Grains are given a quick rinse in 70% alcohol and saline. Those of actinomycetoma are planted on Löwenstein-Jensen medium, and those of eumycetoma on ordinary blood agar or any other rich medium, for example, brain-heart infusion agar, and incubated at 37°C. Subcultures are made on glucose-peptone agar for identification. Colonies formed by bacterial or fungal growth have a special configuration, often retain the color of the grains, and some of them, particularly *M. mycetomatis*, secrete a diffusible pigment in the culture medium.<sup>1</sup>

The biopsy specimen for histologic diagnosis is transferred to the laboratory in 10% buffered formalin. Diagnosis can be made only when grains are seen in the section because their shape, size, and affinity for the stains are quite characteristic (Fig. 78-4).

Ultrastructural studies of mycetoma grains<sup>19,20</sup> show closely packed filaments with an electron-dense matrix between the filaments in some areas. Individual filaments show septation, and their wall consists largely of electron-dense, finely granular material. Some filaments show cytoplasmic organelles, while others appear empty. Neutrophils are closely adherent to the surface of the grain.

Cytoplasmic extracts are refined, dried, reconstituted, and titrated as antigens for serologic diagnosis. Serum is collected from patients and tested for diagnosis or follow-up of treatment.<sup>21</sup> Although enzyme-linked immunosorbent assay (ELISA) has been attempted,<sup>22-24</sup> counterimmunoelectrophoresis remains the serologic test of choice. Precipitation lines in agar develop after 2 hours' incubation at 30°C. They are assessed for their number and intensity of color after staining with naphthalene black.<sup>25</sup> In attempting to improve

the diagnosis of mycetoma, specific oligonucleotide primers encoding the fungal ribosomal RNA of *M. mycetomatis* were developed for use in the polymerase chain reaction (PCR). The test is highly specific and is recommended for species identification of black-grain mycetomas.<sup>26</sup>

## TREATMENT

Prior to starting medical treatment, it is absolutely necessary to determine whether the causal organism of the mycetoma is a bacterium (actinomycetoma) or a fungus (eumycetoma); many cases of treatment failure are attributed to giving the treatment of one to the other. It is worth noting that surgical reduction of a bulky swelling without performing amputation or other drastic surgery will certainly reduce the length of treatment.

Whenever possible, depending on the availability of sophisticated laboratory facilities, in vitro sensitivity of organisms causing mycetoma to antibiotics and chemotherapeutic agents should be assessed.<sup>27</sup> There can be a great difference in the susceptibility of different strains of the same organism to one drug or another. In vitro testing will help select the best possible drug for the treatment of mycetoma.

### Actinomycetoma

The standard treatment for actinomycetoma is a combination of streptomycin sulfate and co-trimoxazole, but if there is no response after 3 weeks, a combination of streptomycin with one of the following drugs is given: diaminodiphenyl sulfone (dapson), sulfadoxine-pyrimethamine (Fansidar), or rifampicin.<sup>28</sup> Injections of streptomycin sulfate are given intramuscularly (IM) at 14 mg/kg/d for the first month and on alternate days thereafter. Each tablet of co-trimoxazole contains 400 mg of sulfamethoxazole and 80 mg of trimethoprim. The usual daily dose is 23 mg/kg/d of sulfamethoxazole and 4.6 mg/kg/d of trimethoprim given in two divided doses. The dose is halved if there is a reduction in either hemoglobin or white blood cell count. Dapsone tablets of 100 mg are given, usually at 1.5 mg/kg morning and evening; in the few cases in which anemia or leukopenia appears, 0.7 mg/kg is given twice daily. Tablets containing 500 mg of sulfadoxine and 25 mg of pyrimethamine are given at 7.5 mg/kg twice weekly. After clinical cure is achieved or when an effect on the bone marrow is noted, the dosage is reduced to 7.5 mg/kg once per week. The dose of rifampicin is 4.3 mg/kg morning and evening.

Amikacin alone and in combination with co-trimoxazole has been used for actinomycetoma patients who have no response to the first-line treatments or have a potentially hazardous site of infection; it is contraindicated when there is hepatic, hearing, or renal impairment.<sup>3,29</sup> The therapy is given in cycles. A cycle is defined as the period of simultaneous administration of amikacin 15 mg/kg/d divided into two daily doses for 3 weeks and co-trimoxazole (35 mg sulfamethoxazole and 7 mg trimethoprim per kilogram per day) for 5 weeks. Twenty-six patients in Mexico have been treated with this therapy. Twenty-one needed one or two cycles of treatment (5 to 10 weeks), and only five needed three cycles (15 weeks). After the treatment was completed, the patients were asymptomatic and remained without further medication.

All patients have been evaluated for periods of between 6 months and 7 years. Side effects were minimal with no gastrointestinal disturbances and normal creatinine clearance rates.

The combination of amoxicillin and clavulanic acid has been reported to be effective for treatment of mycetoma due to *Nocardia brasiliensis* when there is resistance to drugs commonly used, when there is bone or visceral involvement, and in the case of side effects to sulfones or aminoglycosides.<sup>30</sup>  $\beta$ -Lactam resistance in *N. brasiliensis* is mediated by  $\beta$ -lactamase and is reversed in the presence of clavulanic acid.

### Eumycetoma

It would be appropriate to select an antimycotic agent after isolation of the causative fungus if antimycotic testing is available.<sup>5</sup> However, in the case of eumycetoma due to *M. mycetomatis* and *M. grisea*, which constitute the major causative agents in tropical and subtropical Africa, Asia, and South America, the drug of choice is ketoconazole<sup>31,32</sup> at a dose of 200 mg twice daily; no significant side effects or biochemical abnormalities are seen. Ketoconazole, however, may not be as effective in mycetoma caused by *P. boydii*. Liver function tests should be performed regularly every month during treatment in patients treated with an imidazole.

Itraconazole was not effective in the treatment of mycetoma due to *M. mycetomatis* in early reports, but recent studies in Sudan (unpublished data) have shown some success. A successful outcome of treating mycetoma due to *Aspergillus flavus* with itraconazole was reported from the United States.<sup>33</sup> Mycetoma due to *Scedosporium apiospermum* has been treated with voriconazole.<sup>8</sup>

Mycetoma is a chronic infection, and likewise treatment must be continued for a long time. In all cases, treatment should continue for not less than 10 months and may have to be extended for 2 years, depending on the tolerance of the patient for the drug used. Medical treatment of an actinomycetoma can have a favorable result (Figs. 78-5 and 78-6).

### Treatment Follow-up

Patients can be treated at home and be followed in clinic every 2 to 3 weeks. The size of the swelling is measured by tape at the same anatomic point to assess progressive decreases in size, sinuses are counted, and color and free movement of the skin over the swelling are assessed, but an objective response is determined by the number and intensity of precipitating antibodies in the serum by means of counter-immunoelectrophoresis.<sup>25</sup> As recovery progresses, precipitation arcs become fewer and change from strong to faint in appearance until finally they disappear. Actinomycetoma patients should be monitored by determination of the total white cell count and hemoglobin concentration every month.

## PREVENTION AND CONTROL

There is no vaccine against mycetoma agents. Since entry of the causal organisms is often associated with a skin-penetrating injury such as a thorn prick, it was suggested to encourage those exposed to infection, such as field laborers and animal herders, to wear shoes. However, the most effective method of control, at present, is to detect early cases

when swellings are small, excise them, and give concurrent medical treatment to prevent recurrence. In endemic areas, awareness of the disease and its complications should be increased through health education.

# Chromoblastomycosis and Phaeohyphomycosis

TADAHIKO MATSUMOTO

## INTRODUCTION

Human and animal infections caused by fungi whose mycelia or cells in tissue are dark-colored (dark brown, olive, or black) can be separated into four categories: superficial, cutaneous, subcutaneous, and systemic diseases. The term dematiaceous, which had been used to describe dark-colored fungi, was found to be epistemologically incorrect and has been replaced by “phaeoid” (Gr. *phaios*, dusky).<sup>1</sup>

In most cases, the pigment in the cell walls of the hyphae or conidia is melanin, and specifically dihydroxynaphthalene (DHN) melanin appears to be common to most of the medically important phaeoid fungi. In comparison with what is known about the role of fungal melanins in phytopathogenic fungi, current knowledge of their role in infections of humans and lower animals is at an early stage of development. However, recent investigation of the possible effects of fungal melanins in the pathogenesis of the phaeoid fungi has already yielded some interesting results.<sup>2,3</sup> Definitive proof of the involvement of melanin in the virulence of phaeoid fungi awaits further molecular biological studies that specifically alter the DHN-melanin biosynthesis pathway by gene disruption.

The cutaneous and subcutaneous mycoses with etiologic agents that have phaeoid invasive forms are chromoblastomycosis, eumycotic mycetoma (in part; see Chapter 78), and phaeohyphomycosis. Visceral or systemic infections also occur as disseminated cases of phaeohyphomycosis of the internal organs. Phaeoid fungal infections have a broad spectrum of clinical features, ranging in severity from superficial and mild to deep-seated, serious, and fatal.<sup>4</sup>

## ■ Chromoblastomycosis

Chromoblastomycosis is a mycotic infection of cutaneous and subcutaneous tissues characterized by the development in tissue of phaeoid muriform cells by its etiologic agents. The term sclerotic cells, as used for the characteristic cells seen in tissue in chromoblastomycosis, has been replaced by “muriform cells.”<sup>5</sup>

## AGENTS

The principal etiologic agents of chromoblastomycosis are *Cladophialophora* (formerly *Cladosporium*) *carrionii*, *Fonsecaea*

*compactum*, *Fonsecaea pedrosoi*, *Phialophora verrucosa*, and *Rhinocladiella aquaspersa*. Among them, *F. pedrosoi* is the most frequent agent, followed by *C. carrionii* and *P. verrucosa*. *F. pedrosoi* is predominant in warm and humid areas, whereas *C. carrionii* occurs in arid and semiarid zones. *F. pedrosoi* and *P. verrucosa* have been reported as etiologic agents of phaeohyphomycosis as well, the latter also as an etiologic agent of black grain mycetomas. *Fonsecaea compactum* is sometimes considered as a dysgonic strain or variety of *F. pedrosoi*. These fungi are present in soil, decaying wood, and decomposing vegetation.<sup>4,6</sup>

In culture, all these species produce similar dark colonies with short aerial hyphae and gray, green, brown, or black velvety surfaces. These agents are differentiated by their microscopic morphology, physiology, serology (exoantigen tests), and molecular biology.<sup>4,7,8</sup>

## EPIDEMIOLOGY

Although most cases of chromoblastomycosis have occurred predominantly in tropical and subtropical areas, the disease has been reported from the temperate zones of every continent in the world. Brazil and Madagascar are the countries with the highest prevalence. The highest incidence of chromoblastomycosis has occurred in Costa Rica.<sup>9,10</sup> However, partially because of the gradually and steadily rising global temperature and marked increase of immigration and travel, the reported cases of chromoblastomycosis have been spreading from tropical and subtropical areas to temperate areas. Generally it affects the exposed areas of the skin, mostly the distal part of the legs of male outdoor laborers who often work barefooted.

## DISEASE

The primary lesion is a small, pink, scaly papule that occurs at the site of inoculation of the etiologic fungus. The traumatic injury could be very minor or it could have occurred many years previously, more than two decades in some cases, and subsequently forgotten. The papule gradually enlarges to form a superficial erythematous or purplish plaque. The lesion at first may be scaly or verrucous in appearance, but as it progresses it becomes a verrucous nodule. Occasionally, the lesion is pruritic, and when a secondary bacterial infection appears, the patient may complain of pain. Satellite lesions may develop by way of the superficial lymphatics, or by autoinoculation through scratching. New lesions resemble the primary ones and transform themselves into the types of lesions just described. They frequently merge to form a verrucous, sometimes cauliflower-like mass. On the surface, hemopurulent black dots are often observed. Ulceration may occur when a secondary infection or a localized injury to the lesions coexists. Secondary infections also lead to lymphatic stasis, which may result in elephantiasis. Scars may be formed in the center of the lesions when they enlarge centrifugally (Fig. 79-1).

## PATHOGENESIS AND IMMUNITY

Although, in general, chromoblastomycosis is localized at the site of the primary inoculation, the etiologic fungus can break through cutaneous tissue, metastasize to subcutaneous lymphatics or muscle tissue, and disseminate to other organs, including the central nervous system. Early diagnosis of

**FIGURE 79-1** Chromoblastomycosis caused by *Fonsecaea pedrosoi*.

metastasis is of utmost importance in treatment. The tissue response in chromoblastomycosis is not specific for establishing a histopathologic diagnosis. Fundamentally, it is a mixed purulent and granulomatous inflammatory reaction, which may also occur in other mycoses.

The small granulomatous nodules, consisting of epithelioid cells and multinucleated giant cells, are found in the dermis or in subcutaneous tissues. Wood splinters are occasionally encountered in situ. The granulomas may have microabscesses containing polymorphonuclear leukocytes and necrotic debris. The surrounding stroma, infiltrated with lymphocytes, plasma cells, macrophages, and polymorphonuclear leukocytes, may show marked fibrosis, especially in older lesions. In the epidermis, either acanthosis or pseudoepitheliomatous hyperplasia or both are recognized. The hyperplastic epidermis may extend into the affected dermis, forming lips around the necrotic tissue. The stratum corneum is frequently distorted and shows hyperkeratosis and parakeratosis. Cellular infiltrates in the epidermis, consisting of polymorphonuclear leukocytes, may occasionally form keratolytic microabscesses.

In tissue, the phaeoid, round to polygonal, thick-walled, and multicellular muriform cells are the characteristic and diagnostic features of chromoblastomycosis. The muriform cells represent an intermediate vegetative form arrested between yeast and hyphal formation. The muriform cells occur free in tissues or may be contained in giant cells or in microabscesses, as well as in the epidermis, and even in the stratum corneum (Fig. 79-2).

The wide distribution of muriform cells could be explained, in part, by a phenomenon called “transepidermal (or transepithelial) elimination.” This phenomenon causes foreign material (e.g., fungus cells) in the dermis to be eliminated via transepidermal passage without causing any major structural alteration or epidermal degeneration.<sup>11</sup>

**FIGURE 79-2** Phaeoid muriform cells in chromoblastomycosis caused by *Fonsecaea pedrosoi* (periodic acid–Schiff stain).

A morphologic study of the host-parasite interaction in chromoblastomycosis revealed that some of the phagocytosed fungal cells are damaged but that intracellular killing of the fungus is rare. These findings suggested that the tissue form of the etiologic agents of chromoblastomycosis resisted the fungicidal activity of the cutaneous macrophages that possessed the ultrastructural features of stimulated phagocytes.<sup>12</sup>

## DIAGNOSIS

Diagnosis is based on the characteristic clinical appearance of chromoblastomycosis, by the presence of phaeoid muriform cells in tissue, and by the isolation and identification of the etiologic fungi (Fig. 79-3).

The exoantigen test is applicable to identification of cultures in some species; however, none of the reagents are commercially available. Molecular probes are being developed for the phaeoid fungi, but their application is currently limited to taxonomic purposes (see Phaeohyphomycosis).

## TREATMENT AND PROGNOSIS

The treatment of choice is surgical excision of small lesions and antifungal chemotherapy with flucytosine with or

**FIGURE 79-3** In vitro micromorphology of *Fonsecaea pedrosoi*.

without intravenous amphotericin B. As long-term therapy, itraconazole 200 to 400 mg/day effectively controls the disease, although in limited trials saperconazole was reported to be more effective and required shorter treatment courses than itraconazole.<sup>6</sup> The efficacy of fluconazole (100 to 400 mg/day) has not been satisfactory.<sup>13</sup> A recent report from Madagascar on terbinafine (500 mg/day for 6 to 12 months) in the treatment of the 42 Malagasy patients with chromoblastomycosis described promising and encouraging results (a global efficacy of about 75%).<sup>14</sup> Alternate week and combination therapy with itraconazole and terbinafine was effective for some cases of chromoblastomycosis in which patients demonstrated minimal to poor response to monotherapy with oral itraconazole or terbinafine. Flucytosine (100 to 200 mg/kg/day) is effective when combined with itraconazole. Resistance to flucytosine may develop if it is used alone. Antifungal agents under development may play an important role in the treatment of chromoblastomycosis. Agents of chromoblastomycosis are sensitive in vitro to the new triazoles, voriconazole and posaconazole, and also to some of the echinocandins.

Local heat therapy, using a pocket warmer or an electric pad, has been used successfully in cases of chromoblastomycosis. A study of the mechanisms underlying the effectiveness of topical heat therapy suggested that heat killing of the causative organism is unlikely to have been the sole reason for the effectiveness of this modality.<sup>15,16</sup>

Chromoblastomycosis is still notoriously resistant to treatment, with the result that management is extremely frustrating. Clinical type, etiologic species, duration of disease, site of infection, underlying condition of the patient, and experience of the physician are primary factors dictating the type of treatment and the patient's outcome.

## PREVENTION AND CONTROL

The incidence of chromoblastomycosis would be reduced through education, economic development, and early diagnosis and treatment. The low incidence of infections does not justify the development of vaccines, assuming such an approach were feasible.<sup>17</sup>

## ■ Phaeohyphomycosis

Phaeohyphomycosis is an infection of humans and other animals caused by a number of phaeoid fungi, characterized by the basic development of dark-colored filamentous hyphae in invaded tissues. The term phaeohyphomycosis encompasses distinct mycotic infections regardless of the site of the lesion, pattern of tissue response (granuloma or abscess), or taxonomic classification of the etiologic agents.<sup>18</sup>

## AGENTS

Along with the increasing number of immunocompromised patients, the number of genera and species of fungi causing phaeohyphomycosis has been growing. As of 1998, the phaeoid fungi, verified as causing phaeohyphomycosis, comprised 109 species classified in 60 genera, and still growing. Among them, *Exophiala jeanselmei* and *Wangiella dermatitidis* were the most common species, followed by such phaeoid fungus species as

*Alternaria alternata*, *Bipolaris spicifera*, *Curvularia lunata*, *Exophiala moniliae*, *Exophiala spinifera*, *Exserohilum rostratum*, *Phaeoacremonium parasiticum*, *Phialemonium obovatum*, and *Phialophora repens*.<sup>19</sup>

## EPIDEMIOLOGY

In contrast to chromoblastomycosis, cases of phaeohyphomycosis occur with equal frequency in tropical, subtropical, and temperate areas, partly because of the opportunistic nature of its etiologic agents. Previously, the distribution of the pathogenic phaeoid fungi was generally believed to be limited to tropical and subtropical areas. However, there have been several reports of the isolation of potentially pathogenic phaeoid fungi from nonclinical sources. They have provided new ecologic insights into the global distribution of this particular group of fungi.<sup>4</sup>

## DISEASE

Phaeohyphomycosis is a cosmopolitan disease. The patients are usually adults, about half of whom seem to be immunologically compromised by such associated underlying diseases as diabetes mellitus, tuberculosis, leprosy, acquired immunodeficiency syndrome (AIDS), lymphoma, and leukemia. Some patients appear to be locally compromised because of the application of topical corticosteroids. The lesions may occur in almost any part of the body, often in exposed parts, especially the upper arms. Inoculation of the agent is considered to be caused by wounds made by contaminated plant materials, so that occasionally patients can recall the history of an injury at the site of the lesion.

The most common and typical lesions are cutaneous or subcutaneous cysts or abscesses, frequently caused by *E. jeanselmei*. The primary lesion occurs as a single, discrete, asymptomatic small nodule. This is palpable under the smooth and slightly elevated skin. The nodule gradually evolves to become an encapsulated, fluctuant abscess with a liquefied center (Fig. 79-4). The overlying epidermis is hardly affected, but, exceptionally, formation of a sinus tract or ulceration is observed. Occasionally, a granulomatous, slightly elevated plaque may appear when the main site of the lesion is in the epidermis and dermis. Less frequently, it is manifested as a small verrucous nodule, or a

**FIGURE 79-4** Subcutaneous phaeohyphomycosis caused by *Exophiala jeanselmei*.

verrucous plaque consisting of coalesced nodules, which resembles the clinical appearance of chromoblastomycosis.

Lymph node involvement and dissemination are rare. However, phaeohyphomycosis may occur in the central nervous system or other internal organs, such as the liver, lungs, or pancreas. It may appear as a hematogenous metastasis from cutaneous or subcutaneous infections, or without any visible lesions. Human infections caused by *W. dermatitidis* have been equally distributed between cutaneous and subcutaneous infections, and systemic involvement. *W. dermatitidis* should be regarded as a dermatropic and neurotropic pathogen.<sup>5,20</sup>

## **PATHOGENESIS**

Cyst or abscess formation is mainly confined to the dermis and adjacent subcutaneous tissue. Three stages have been described: (1) a tuberculoid phase, (2) a stellate abscess, and (3) a fluctuant abscess. In the primary lesion, a hypercellular tubercle composed mainly of epithelioid cells and foreign body giant cells is formed. Scattered foci of necrosis follow, accompanied by acute and chronic cellular infiltrations, and stellate abscesses develop. The stellate abscesses coalesce to transform themselves into a fluctuant abscess.<sup>21</sup>

The abscess is surrounded by a thick wall. The inner layer is made up of a combination of epithelioid cells, macrophages, giant cells of foreign body and Langhans types, and neutrophils. The middle layer is composed predominantly of vascularized scar tissue surrounded by an outer layer of hyalinized fibrous tissue. The center of the abscess contains necrotic debris mixed with polymorphonuclear leukocytes. Foreign plant material, as in chromoblastomycosis, may be present. The granulomatous lesions in the middle to upper dermis mainly consist of epithelioid and giant cells that are covered by the necrotic epidermis. Pseudoepitheliomatous hyperplasia, hyperkeratosis, parakeratosis, and acanthosis overlying the upper dermal granuloma are recognized in phaeohyphomycosis. These appear clinically as verrucous plaques resembling chromoblastomycosis.

The pigmented fungal elements show a variety of morphologies in the tissue of phaeohyphomycosis. They may be dark-walled, short, septate, branched or unbranched hyphal elements, catenulate spherical cells (toruloid or moniliform hyphae), isolated spherical cells that have divided by budding or by septation in a single plane, or various combinations of any of these (Fig. 79-5). The spherical yeastlike cells occasionally resemble the muriform cells of chromoblastomycosis, but differ by having thinner cell walls, septation in only one plane, and frequently a catenulate morphology. It is important to note that mycoses caused by phaeoid fungi are variable and that a single fungus species may cause more than one type of disease. Chromoblastomycosis and phaeohyphomycosis represent extremes of a continuum of infections caused by phaeoid fungi.<sup>17</sup>

The brown color of the fungal elements, generally easily observable in hematoxylin and eosin-stained tissue slides, is lighter than that of chromoblastomycosis and is often overlooked. Periodic acid-Schiff, Gomori's methenamine silver, or other stains for fungi may be required to detect the fungal elements in such a case. If questions should arise concerning the pigmentation of the mycelium in tissue sections, the Fontana-Masson silver stain, specific for melanin, may be used to advantage. Mycelium that appears to be hyaline in

**FIGURE 79-5** Septate mycelium in cutaneous phaeohyphomycosis caused by *Wangiella dermatitidis* (periodic acid-Schiff stain).

hematoxylin and eosin-stained sections may give a positive reaction for melanin.<sup>22</sup>

## **DIAGNOSIS**

Diagnosis of phaeohyphomycosis is based on the presence of phaeoid hyphae in tissue and by the isolation and identification of compatible etiologic fungi (Fig. 79-6). The exoantigen test is applicable to identification of cultures in some phaeoid fungi; however, none of the reagents are commercially available. Molecular probes are also being developed for some of the agents of phaeohyphomycosis, but their application is currently limited to taxonomic purposes.

Many physicians regard molecular diagnosis as infallible, and several groups advocate use of the 18S rRNA gene locus as the sole PCR target necessary for fungal diagnostics. However, molecular identification of medically important fungi should be confirmed by sequence analysis of an additional rRNA gene locus, such as the internal transcribed spacer (ITS) region(s). For example, the molecular interrelationships of one group of phaeoid molds and yeasts, *Exophiala spinifera* clade, were studied using sequences of the small-subunit (SSU) and ITS domains of ribosomal DNA. The resulting proposals were three new species, including *E. oligosperma*, redefinition of *E. jeanselmei*, and two new combinations: *E. exophialae* and *E. heteromorpha*.<sup>23</sup>

**FIGURE 79-6** In vitro micromorphology of *Exophiala moniliae*.

## TREATMENT AND PROGNOSIS

Successful treatment of cutaneous and subcutaneous phaeohyphomycosis is achieved by simple surgical excision. However, cases of systemic and disseminated phaeohyphomycosis are serious and have a high rate of mortality. Antifungal chemotherapy with either amphotericin B or flucytosine or combination therapy with these agents should be attempted. Treatment with fluconazole, itraconazole, ketoconazole, or terbinafine has been reported with mixed results.<sup>19,24</sup> Clinical responses were well correlated with in vitro susceptibility test results; however, resistance did not preclude clinical response.

As in the case of chromoblastomycosis, antifungal agents under development may play an important role in the treatment of phaeohyphomycosis. Some of the fungi causing phaeohyphomycosis are sensitive in vitro to the new triazoles, voriconazole and posaconazole, and also to some of the echinocandins.

Local heat therapy, using a pocket warmer or an electric pad, may also be applied to cutaneous and subcutaneous phaeohyphomycosis, even though some of the etiologic fungi possess considerable thermotolerance.<sup>15,16</sup>

## PREVENTION AND CONTROL

Prevention and control are not practical for phaeohyphomycosis. Owing to the cosmopolitan, ubiquitous nature of the fungi causing phaeohyphomycosis, it is not feasible to attempt their eradication.<sup>17</sup>

## ACKNOWLEDGMENT

Dr. Libero Ajello, former Director of the Division of Mycotic Diseases and now a Guest Researcher of the Mycotic Diseases Branch, Division of Bacterial and Mycotic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia, provided helpful suggestions and revision of the manuscript.

# Histoplasmosis, Blastomycosis, Coccidioidomycosis, and Cryptococcosis

GREGORY M. ANSTEAD  
JOHN R. GRAYBILL

## ■ Histoplasmosis

### AGENT

*Histoplasma capsulatum* is a thermally dimorphic fungus found in soil enriched by guano of birds and bats. The fungus can remain viable for years in the soil.<sup>1</sup> It grows as a mold in nature and on culture media such as Sabouraud dextrose agar. In the human body, it is found as a small budding yeast.<sup>2</sup> Two varieties have been recognized, *H. capsulatum* var. *capsulatum* and *H. capsulatum* var. *duboisii*.

### EPIDEMIOLOGY

Histoplasmosis due to *H. capsulatum* var. *capsulatum* has a wide distribution in North and South America and has been reported in Asia, Africa, and Europe.<sup>3</sup> In the United States, the endemic region is centered around the Ohio and Mississippi River Valleys. In most cases, histoplasmosis is a benign, self-limited pulmonary infection. Dissemination is uncommon, occurs mainly in people with impaired cell-mediated immunity, and may represent either primary infection in immunosuppressed people or recrudescence from viable yeast within old, healed lesions. In endemic areas, 2% to 5% of human immunodeficiency virus (HIV)-infected patients may develop disseminated histoplasmosis.<sup>4</sup> In a case-control study of HIV-infected people with histoplasmosis, those with occupational exposure to soil contaminated with bat or bird droppings had a 3.3 times greater risk of acquiring the infection.<sup>5</sup> People treated with tumor necrosis factor antagonists, children with cancer, and pregnant women represent newly recognized susceptible hosts for histoplasmosis.<sup>6-8</sup> Histoplasmosis has also been increasingly diagnosed in travelers to Latin America, Africa, and the Caribbean, especially those who engage in spelunking.<sup>9</sup> African histoplasmosis, caused by var. *duboisii*, is endemic to central and western Africa between the latitudes

15°N and 10°S, roughly between the Sahara and Kalahari deserts; the majority of cases have been reported from Nigeria.<sup>10</sup> The ecology of the var. *duboisii* is not well-known, but it has been found in bat caves.<sup>10</sup> Var. *duboisii* spares the lungs and attacks the bone, skin, and soft tissue.<sup>11</sup>

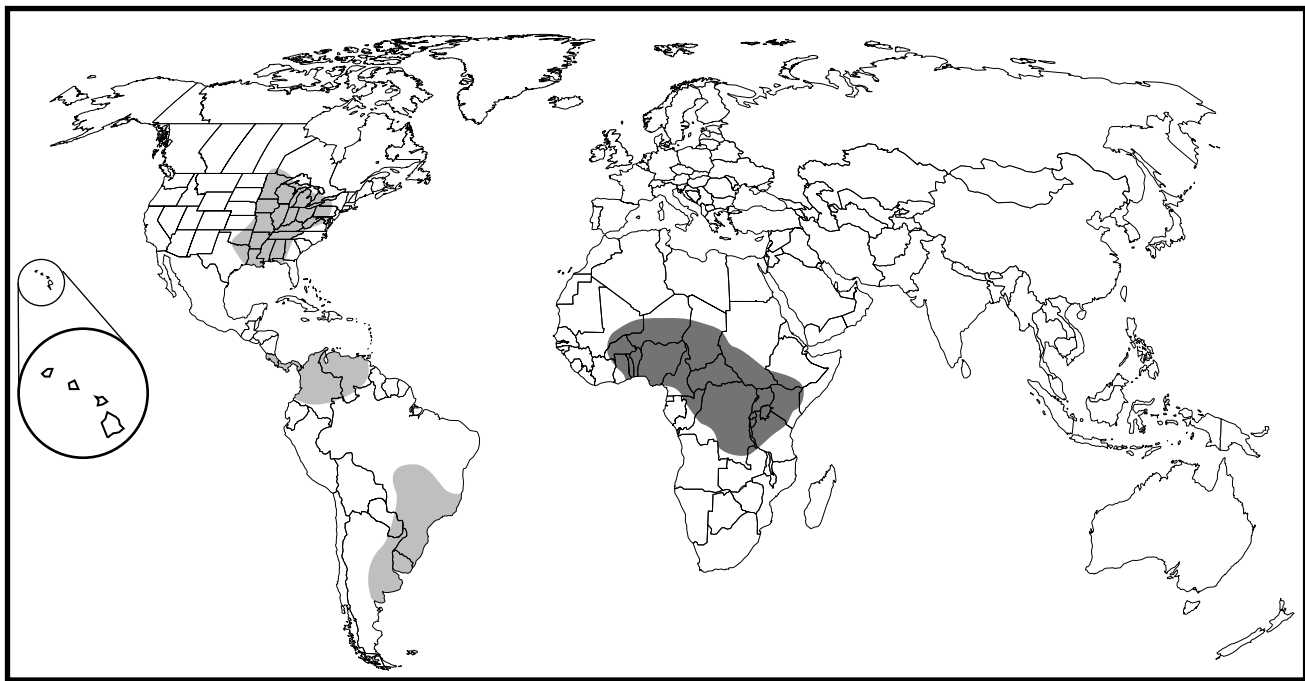

### DISEASE

More than 95% of immunocompetent people remain asymptomatic following infection with *H. capsulatum* var. *capsulatum*. In symptomatic cases, self-limited pulmonary illness usually develops with fever, malaise, cough, and chest pain. Chest radiographs show focal infiltrates with hilar or mediastinal lymphadenopathy.<sup>3</sup> The degree of exposure and immune status of the host determine the likelihood of having mild or severe disease. In cases with heavy exposure to *H. capsulatum* or severe immunosuppression, symptomatic disease is common, including severe pneumonia, with adult respiratory distress syndrome (ARDS) and respiratory failure.<sup>12,13</sup> In these patients, chest radiographs show a miliary pattern. Rheumatologic manifestations may be associated with primary infection.

Chronic pulmonary histoplasmosis is a subacute progressive or recurrent pneumonia associated with night sweats, fatigue, productive cough, and apical lung infiltrates with fibrosis and cavitation.<sup>14,15</sup> It often occurs in the setting of chronic obstructive pulmonary disease and may in part be an aberrant necrotizing reaction to *H. capsulatum* antigens. Although patients may succumb from pulmonary disease, dissemination is exceedingly rare. A rare but devastating complication of resolution of infection in the mediastinal lymph nodes is progressive mediastinal fibrosis.<sup>16</sup>

Disseminated infection is the most serious form of the disease, and it manifests as prolonged fever, weight loss, mucocutaneous lesions, hepatosplenomegaly, lymphadenopathy, pneumonia, meningoencephalitis, adrenal insufficiency, occasional intestinal masses or ulcerative lesions, and, in some patients, an acute sepsis-like illness with disseminated intravascular coagulation (DIC).<sup>12,17</sup> Skin lesions, uncommon in U.S. patients with histoplasmosis (<10% of cases), are more frequently reported in patients from Latin America (38%–85% of patients), and this may be due to genetic differences in the fungal strains.<sup>18</sup> Other described manifestations of histoplasmosis include endocarditis, pericarditis, choroiditis, and central nervous system (CNS) mass lesions.<sup>19,20</sup> Laboratory abnormalities are common, with anemia, leukopenia, thrombocytopenia, and elevated liver enzymes. Very high serum concentrations of lactate dehydrogenase (LDH) have been detected in patients with the acquired immunodeficiency syndrome (AIDS).<sup>21</sup> In AIDS patients with pneumonia and high LDH concentrations, histoplasmosis and pneumocystosis are the leading diagnostic considerations. Table 80-1 summarizes the clinical manifestations and treatment. Factors associated with severe histoplasmosis (causing shock, respiratory failure, or death) in patients with AIDS include high creatinine level and low serum albumin.<sup>22</sup>

African histoplasmosis, caused by *H. capsulatum* var. *duboisii*, is characterized by skin, subcutaneous, and bone disease. Chronic ulcers and tender subcutaneous nodules are common. Bone infection manifests as multiple osteolytic lesions, occurring most commonly in the femurs, ribs, vertebrae, humeri, sternum, tibiae, skull, and wrist bones. Often, there

**Table 80-1** Clinical Manifestations and Treatment of Histoplasmosis

Disease	Clinical Findings	Treatment
Primary pulmonary histoplasmosis	Mild disease; cough, chest pain, fever, hilar or mediastinal lymphadenopathy, pulmonary infiltrates	Self-limited; no treatment; if symptoms persist, ketoconazole 400 mg/day or itraconazole 200 mg/day for 2–3 wk
Severe primary pulmonary histoplasmosis (high exposure)	Severe pneumonia, ARDS, respiratory failure, miliary pattern on chest x-ray	Amphotericin B 1 mg/kg and prednisone 40–60 mg/day for 2 wk
Chronic pulmonary histoplasmosis	Fever, weight loss, productive cough, apical fibrotic and cavitary lung infiltrates	Itraconazole 400 mg/day, or ketoconazole 400 mg/day for 6–12 mo, or amphotericin B for a total dose of 35 mg/kg
Disseminated histoplasmosis	Prolonged fever, weight loss, skin lesions, hepatosplenomegaly, pneumonia, sepsis syndrome, meningoencephalitis	Less severe: itraconazole 400 mg for 3 mo; severe: amphotericin B 1 mg/kg/day followed by itraconazole 400 mg/day for 3–6 mo; in AIDS patients: maintenance therapy with itraconazole indefinitely
Histoplasmosis	Mostly asymptomatic coinlike lesions in the lungs	No treatment unless symptomatic; ketoconazole or itraconazole 400 mg/day for 6 mo
Fibrosing mediastinitis	Pressure on mediastinal structures; progressive fatal complication	No medical treatment; ? surgery for decompression

ARDS, adult respiratory distress syndrome.

are chronic sinus tracts from the bony lesions to the skin.<sup>11</sup> There is no clear correlation between compromised host immune status and infection with var. *duboisii*.<sup>23</sup>

## **PATHOGENESIS AND IMMUNITY**

Microconidia of *H. capsulatum* (and, to a lesser degree, macroconidia and small hyphal elements) are inhaled into the lungs, where they reach the alveolar spaces and transform into yeasts.<sup>24</sup> Neutrophils and alveolar macrophages form the earliest line of host defense, in which they engulf the organisms and contain them. Neutrophils are more active against the fungus than are macrophages. After phagocytosis they exert their antifungal activity through poorly understood intracellular killing mechanisms that do not involve respiratory burst.<sup>25</sup> Macrophages exert less efficient antifungal activity, and yeast forms can multiply within them, leading to their lysis and infection of new cells.<sup>26</sup> The major defense mechanisms involve a specific T cell immune response.<sup>27</sup> T helper (CD4) and, to a much lesser degree, cytotoxic (CD8) T lymphocytes are the main cells involved in controlling and clearing the infection. CD4 cells are crucial to resolving the infection, whereas CD8 cells have an additive effect for optimal eradication of the organisms. This effect has been demonstrated in mice and observed in patients with CD4 deficiency, including patients with AIDS.<sup>27–29</sup> Following pulmonary infection, organisms spread through lymphatics to the regional lymph nodes and hematogenously to other organs. In immunocompetent people, the typical pathologic findings resemble tuberculosis, with granulomas occasionally evolving to caseous necrosis. These granulomas heal with fibrosis and can calcify. An immunologic reaction to the organism or antigens released from killed organisms is likely responsible for arthritis, pericarditis, and erythema nodosum associated with the primary infection. Patients with AIDS show a minimal inflammatory response, and masses of organisms are commonly found.<sup>12,30</sup>

## **DIAGNOSIS**

The diagnosis of histoplasmosis based on cultures suffers from low sensitivity and slow growth of the organism (2 to 6 weeks). In disseminated disease, organisms can be recovered from blood, bone marrow, lung, liver, and often urine. Isolator blood cultures are preferable to routine media. Tissue biopsies stained with Gomori's methenamine silver (GMS) have high sensitivity and provide a more rapid diagnosis than cultures; however, they are not specific to *Histoplasma*. In overwhelming infection, as occurs often in AIDS, demonstration of the organism in the buffy coat of blood leukocytes by Giemsa stain may be a quick and simple method to diagnose disseminated disease. In histopathologic specimens from patients with *H. capsulatum* var. *duboisii* infection, the organism has thick, doubly contoured walls and may show chain formation and "hourglass" or "figure-eight" budding.<sup>11</sup>

Serologic techniques, such as immunodiffusion (ID) and complement fixation antibody tests (CFTs), are useful methods for diagnosis of histoplasmosis in the immunocompetent patient. A CFT titer greater than 1:32 is highly suggestive of infection. Titers from 1:8 to 1:16 are less specific.<sup>31</sup> The ID method is less sensitive, and detection of antibodies appears later in the course of infection. These antibodies crossreact

with those in *Blastomyces dermatitidis* and *Coccidioides immitis* infections, and because antibody titers are usually low in patients with immune suppression, these antibody-based methods have been replaced in the United States by a direct test for *Histoplasma* antigen.<sup>32</sup> Detection of *Histoplasma* antigen by radioimmunoassay or enzyme immunoassay in serum and urine is highly sensitive and specific in disseminated disease in AIDS patients.<sup>33</sup> Monitoring antigen levels is also useful for the diagnosis of relapse in AIDS patients.<sup>33</sup> Antigen assays are less useful in nondisseminated disease. A polymerase chain reaction-based diagnostic method has been described.<sup>34</sup>

## **TREATMENT AND PROGNOSIS**

Practice guidelines for the treatment of histoplasmosis were published in 2000.<sup>35</sup> For immunocompetent patients with severe acute pulmonary histoplasmosis, amphotericin B (0.7 mg/kg/day) or liposomal amphotericin B with prednisone (60 mg/day for 2 weeks) is recommended as initial therapy. Amphotericin B has a response rate of more than 75% in HIV- and non-HIV-infected patients. A rapid response in less than 1 week has been observed.<sup>36</sup> As the patient improves, itraconazole (200 to 400 mg/day) can be given to complete a 12-week course. In mild or moderately severe acute disease, itraconazole is the drug of choice, given in a dose of 400 mg/day initially and then 200 mg/day for a total of 6 to 12 weeks in non-AIDS patients. For immunocompetent patients with disseminated disease, a similar therapeutic approach should be applied, but the duration of treatment should be extended to 6 to 18 months. For chronic pulmonary histoplasmosis, itraconazole (200 to 400 mg/day) should be given for 12 to 24 months. In AIDS patients, prolonged suppression with itraconazole should be used.<sup>37</sup> Fluconazole is also effective, but it is less potent than itraconazole. High-level fluconazole resistance and the development of fluconazole resistance while on therapy have been documented with *H. capsulatum*.<sup>38,39</sup> For *H. capsulatum* meningitis, initial therapy with amphotericin B (to complete 35 mg/kg/day over 3 or 4 months) is recommended, followed by continuation therapy with high-dose fluconazole (800 mg/day) for another 9 to 12 months.<sup>35</sup>

Blood cultures and antigen revert to negative more rapidly in patients given liposomal amphotericin than itraconazole.<sup>40</sup> The recommended dose of liposomal amphotericin B is 3 mg/kg/day.<sup>41</sup> In a study of HIV-infected patients, liposomal amphotericin B was found to be less toxic and more effective than conventional amphotericin B.<sup>41</sup> The newer triazoles, voriconazole and posaconazole, have been used successfully in the treatment of histoplasmosis, but the number of patients who have been evaluated is too small to be conclusive. In lymphocyte-depleted mice, posaconazole was as effective as amphotericin B and more effective than itraconazole.<sup>42</sup> In recent years, there has been interest in discontinuing chronic suppressive therapy in patients who achieved immune reconstitution on highly active antiretroviral therapy (HAART).<sup>43</sup> Subjects were eligible if they had received 12 months of antifungal treatment, 6 months of HAART, had a *Histoplasma* antigen level less than 4.1 units, and had a CD4 count greater than 150 cells/ $\mu$ L. Thirty-two subjects stopped suppressive therapy. In 65 patient-years of observation, there were no relapses. The median CD4 count was 389 cells/ $\mu$ L at cessation of observation.

Thus, stopping suppressive therapy appears to be safe in patients who have recovered their CD4 counts with HAART.

In non-AIDS cases of severe acute pulmonary histoplasmosis with ARDS, steroids may be used as adjunctive therapy.<sup>13</sup> However, steroids have no role in the management of histoplasmosis in AIDS because the infiltrates are composed primarily of massive numbers of organisms rather than host inflammatory cells. Table 80-1 summarizes treatment options in different clinical settings. Rheumatologic manifestations respond to anti-inflammatory drugs without antifungals.

The prognosis is excellent for acute pulmonary (self-limited) disease in the immunocompetent patient. Fibrosing mediastinitis is usually slowly progressive and often fatal. Acute disseminated disease is usually fatal if untreated. In a case-control study of HIV-infected patients with histoplasmosis, a history of chronic medical conditions or herpes simplex infection were associated with poor outcome; conversely, administration of trimethoprim/sulfamethoxazole prophylaxis for pneumocystosis decreased the risk of a poor outcome.<sup>5</sup> In another study of AIDS patients with histoplasmosis, dyspnea, thrombocytopenia, and LDH level twice the upper limit of the normal range were associated with death.<sup>44</sup>

Few data are available regarding the treatment of African histoplasmosis. The disease is responsive to amphotericin B, ketoconazole, and trimethoprim/sulfamethoxazole.<sup>11</sup>

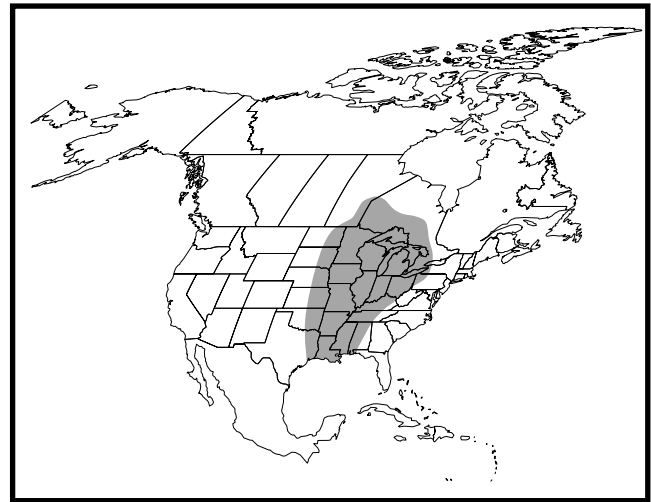

## PREVENTION AND CONTROL

Human-to-human transmission of histoplasmosis is not a significant means of infection. Currently, there is no vaccine for histoplasmosis. A study of antifungal prophylaxis in AIDS patients in highly endemic areas showed itraconazole to be highly effective in preventing histoplasmosis.<sup>45</sup> However, with the sharp decline in AIDS (and histoplasmosis) due to HAART, the cost of itraconazole for prophylaxis cannot be justified.

## ■ Blastomycosis

### AGENT AND EPIDEMIOLOGY

*Blastomyces dermatitidis* is a dimorphic fungus that occurs commonly along the river estuaries from Minnesota to Mississippi in the United States, but it is also found in scattered areas of Europe, Asia, Latin America, and Africa. *Blastomyces dermatitidis* is found in nature predominantly in areas with proximity to water sources.<sup>46</sup> Within its endemic area, there are hyperendemic foci that have conditions that favor the growth of the fungus: sandy, acidic soil, low elevation, and multiple bodies of water.<sup>47</sup> Exposure to soil containing the fungi has been associated with large outbreaks, with 48 (51%) of 95 potentially exposed people becoming infected in one outbreak.<sup>48</sup> Exposure to beaver lodges was a specific risk factor in one outbreak,<sup>48</sup> but the specific association to beavers has been disputed.<sup>49</sup> Dogs are highly susceptible to blastomycosis and may act as sentinels in point-source outbreaks.<sup>50</sup> Blastomycosis has also been transmitted to a human by the bite of a dog with an oral lesion.<sup>51</sup> In the United States, African American race has been suggested as a risk factor for symptomatic disease.<sup>47</sup> South Africa is the most common region for blastomycosis outside the United States.

*Blastomyces dermatitidis*

■ North American blastomycosis

African isolates do not contain the cell wall antigen A, which is common to North American forms and is detected in immunodiffusion tests.<sup>52</sup>

### DISEASE AND PATHOGENESIS AND IMMUNITY

Infection is by inhalation with the development of pneumonia over several weeks. This is associated with mass or alveolar infiltrative lesions, which may resolve over several weeks or progress to more severe pneumonia, with weight loss, night sweats, sputum production, and chest pain.<sup>53</sup> All of this may resemble tuberculosis. Alveolar macrophages can inhibit the phase transition of the conidia into yeast cells, and neutrophils are also active against *B. dermatitidis*.<sup>54,55</sup>

Chronic forms of blastomycosis include cavitary lung disease and dissemination, primarily to the skin but also to the bones and genitourinary system, in which prostatitis occurs relatively frequently. Skin lesions are nodular or ulcerative and contain mixed microabscesses and granulomas (Fig. 80-1). Fewer than 10% of chronic infections have brain involvement. The involvement of the reticuloendothelial system and adrenal glands is uncommon. Chronic skin lesions are especially common in African patients.<sup>52</sup>

Athymic mice fail to control infection, emphasizing the necessity of cell-mediated immunity to control the infection.<sup>56</sup> In athymic mice, the conidia are inhibited by granulocytes, providing some early defense against transition to yeasts. However, once transition to yeasts has occurred, athymic mice are much more susceptible to progressive disease than immunocompetent mice. Nevertheless, blastomycosis is rare in patients with AIDS or conditions with depressed cell-mediated immunity. In these patients, however, the disease is much more aggressive. This severity of illness is probably due to the underlying immunodeficiency rather than differences among isolates; two isolates with identical DNA types caused very different disease in an immunocompetent person and in an AIDS patient.<sup>57</sup> Pappas and colleagues<sup>58</sup> reported in 1992 only 15 patients with blastomycosis in the setting of AIDS in

**FIGURE 80-1** Blastomycotic facial lesions (arrows).

a survey of 10 medical centers, 6 of which were in the endemic area. In these patients, blastomycosis was an opportunistic infection that appeared late in the course of AIDS and included local pulmonary infection (7 patients) and disseminated disease (8 patients). Of those with dissemination, 75% had CNS involvement, which is most uncommon in patients without AIDS. Since then, there have been few patients reported with AIDS and blastomycosis. Diabetes has also been suggested as a risk factor for blastomycosis.<sup>59</sup>

The WI-1 cell wall protein (renamed BAD1), which mediates cellular adhesion, has been recognized as an indispensable virulence factor for *B. dermatitidis*. BAD1 is expressed only on the yeast forms of the fungus and is the main antigenic target for both cellular and humoral immune responses.<sup>60</sup> BAD1 interferes with host immune response by suppressing phagocyte release of tumor necrosis factor- $\alpha$  through transforming growth factor- $\beta$ -dependent and -independent mechanisms.<sup>61</sup> Immunization studies in mice show that administration of WI-1 knockout yeasts affords a high degree of protection after rechallenge with wild-type yeast.<sup>60</sup>

## DIAGNOSIS

With its myriad clinical presentations, the diagnosis of blastomycosis is often delayed, even in endemic areas. In a

series of 132 patients from Mississippi, in only 18% of cases was blastomycosis correctly suspected at the initial patient evaluation.<sup>59</sup>

Diagnoses may be readily made by examination of wet mounts of the sputum digested with potassium hydroxide and by culture. In a study comparing diagnostic methods for blastomycosis, pulmonary cytology was the most successful method for making a diagnosis; culture was negative in one-third of cases.<sup>62</sup> On fungal culture media, such as Sabouraud dextrose agar, *B. dermatitidis* grows readily in the mycelial form at 25°C with detection of colonies after 10 to 18 days and in the yeast form at 37°C. Serologic methods have been problematic because of cross-reactivity of complement fixation antibodies with antigens of *Histoplasma capsulatum*. Two antigens have been analyzed for use in serodiagnosis. The first, A antigen, is prepared from cells that naturally autolyze, and the second (BAD1) is a 120-kDa protein eluted from sodium dodecyl sulfate–polyacrylamide electrophoresis gels.<sup>63</sup> The significance of the absence of antigen A from South African isolates of *B. dermatitidis* is unclear.<sup>52</sup> Antibodies to antigen A are detected by enzyme-linked immunosorbent assay (ELISA) in more than 70% of U.S. patients.<sup>64</sup> Antibodies to the A antigen cross-react extensively in serum from patients with other mycoses. BAD1 is cross-reactive with the serum of only 3% of patients with sporotrichosis, histoplasmosis, candidiasis, or coccidioidomycosis.<sup>65</sup> Due to poor sensitivity and specificity, serologic testing is not useful for the diagnosis of blastomycosis. An antigen test for *B. dermatitidis* has been developed, but the clinical value of this assay is uncertain.

## TREATMENT AND PROGNOSIS

Practice guidelines for the management of blastomycosis were published in 2000.<sup>66</sup> For those with severe pneumonic blastomycosis, life-threatening disseminated disease, or in those patients who fail azole therapy, the use of amphotericin B (0.7 to 1 mg/kg/day; total dose, 1.5 to 2.5 g) is appropriate.<sup>66</sup> After the condition of the patient stabilizes, a switch to itraconazole is appropriate. Excellent clinical responses (more than 90%, with few relapses) have been seen with itraconazole at 400 mg/day given for 6 months in immunocompetent patients.<sup>67</sup> For patients with AIDS or immunosuppression, chronic therapy should be continued to prevent relapse. Patients with AIDS and blastomycosis or those with disseminated disease involving the CNS should be treated initially with amphotericin B.<sup>46,58</sup> After stabilization, a switch to an antifungal azole, preferably itraconazole, is appropriate. The duration of therapy, especially in patients with immune reconstitution on HAART, is unclear. Ketoconazole is effective in some patients but has been shown to fail frequently in CNS blastomycosis, even at doses up to 600 mg/day.<sup>68</sup> Although blastomycosis may respond to fluconazole, responses are less than with itraconazole (which has not been evaluated in CNS disease). Pappas and associates<sup>69</sup> found that of 23 patients evaluated for fluconazole response, in only 15 (65%) was treatment successful. This result includes 8 (62%) of 13 patients treated with 200 mg/day and 7 of 10 patients who received 400 mg/day. Some patients were treated for more than 6 months. Some of those who responded to fluconazole had failed prior therapy with other antifungals.<sup>69</sup> Patients with mild to moderate disseminated blastomycosis that does not involve the CNS should be treated with itraconazole

(200 to 400 mg/day) for at least 6 months. Those with blastomycotic osteomyelitis should receive azole treatment for at least 1 year. There is no published clinical experience with voriconazole, posaconazole, or the echinocandins. In a series from Canada, the mortality rate in patients with blastomycosis was 6.3%, but in a study from Missouri the mortality rate was 44%.<sup>47,70</sup> The mortality rate is strongly influenced by factors that delay diagnosis, such as the initial lack of recognition of the disease in regions of lower incidence.<sup>47</sup>

## ■ Coccidioidomycosis

### AGENT AND EPIDEMIOLOGY

*Coccidioides immitis* is a dimorphic fungus with an endemic range in the Americas that encompasses semiarid to arid life zones with warm summers and mild winters, principally in the southwestern United States and northern Mexico.<sup>71</sup> The fungus is also found in areas of Argentina, Brazil, Colombia, Guatemala, Honduras, Nicaragua, Paraguay, and Venezuela.<sup>72</sup> Hyperendemic areas include Kern County in the San Joaquin Valley of California (the origin of the synonym, valley fever) and Pima, Pinal, and Maricopa Counties in Arizona. Major cities within these hyperendemic areas include Bakersfield, California, and Phoenix and Tucson, Arizona. There is a relationship between climatic conditions and the incidence of coccidioidomycosis. A period of moisture is required for the fungal hyphae to grow in the soil, but during a subsequent dry period the hyphae die, leaving viable arthroconidia (spores). Some spores are dispersed by natural forces (wind and earthquakes) or by anthropogenic disturbance of the soil.<sup>73</sup>

People in occupations that have soil exposure are at the greatest risk, including agricultural and construction workers

*Coccidioides immitis*

■ Coccidioidomycosis

and archaeologists. The latter group may become infected by disturbing soil that has been at rest for many years.<sup>74</sup> *Coccidioides immitis* can also infect primates, dogs, cats, and livestock. In Arizona, the rate of coccidioidomycosis doubled between 1997 and 2001, perhaps due to weather conditions favorable to arthroconidial dispersal.<sup>73</sup> Epidemics of coccidioidomycosis have occurred after natural disasters that generate dust clouds, such as a dust storm in the San Joaquin Valley in 1977 and the Northridge, California, earthquake of 1994.<sup>75,76</sup> For unclear reasons, a large epidemic of coccidioidomycosis occurred in California from 1992 to 1995 in which the incidence of infection was 10 times the usual rate.<sup>77</sup> Until recently, coccidioidomycosis was considered a common infection primarily of the immunocompetent host, with fewer than half of those exposed developing symptoms and very few developing progressive disease. Recently, particularly in Arizona, there has been a greatly increased risk of infection associated with AIDS.<sup>78</sup> The major risk factor for developing coccidioidomycosis in patients with AIDS is depression of the CD4 count. Length of residence in Arizona and prior positive skin test were not factors.<sup>79</sup> Newly described risk groups for coccidioidomycosis include organ transplant recipients who received *Coccidioides*-infected organs, patients treated with tumor necrosis factor antagonists, and travelers to the southwestern United States and Mexico.<sup>6,9,80</sup> Another species in the genus *Coccidioides*, *C. posadasii*, has been identified and is thought to produce an identical spectrum of human disease.<sup>81</sup>

### DISEASE AND PATHOGENESIS AND IMMUNITY

The small arthroconidia are inhaled, ingested by pulmonary macrophages, and convert to a round cell that enlarges over 3 or more days. At the conclusion of this period, it is a large cell (spherule), 8 to 30  $\mu\text{m}$  in diameter, with thick outer walls and contains hundreds of asexual endospores. This cell ruptures and dispersing the endospores, thereby initiating the endospore–spherule cycle.<sup>77</sup>

Following rupture of the spherule, the liberated endospores are strongly chemotactic to neutrophils, but the neutrophils are unable to effectively kill the endospores. Ultimately, the infection is controlled by cell-mediated immunity. However, this control may not occur until after the organism has disseminated hematogenously to the meninges, bones, skin, or other soft tissues. In immunocompetent patients, more than 60% of coccidioidomycosis cases are asymptomatic, and the majority of the remainder of patients have nonspecific complaints including fever, pleuritic substernal chest pain, cough, malaise, anorexia, or chills. This illness may be attributed to “flu,” and medical attention is often not sought.<sup>82</sup> Pulmonary infiltrates can take multiple forms, are commonly associated with hilar adenopathy, and may also be associated with pleural effusions. Up to 25% of men and 4% of women patients have immune complex-mediated manifestations, including erythema nodosum or erythema multiforme or both. Arthralgias may also occur, as well as eosinophilia, comprising up to 20% of the leukocyte count. Untreated, pneumonia usually resolves within 6 to 8 weeks. Low titers of antibodies are common. There is no antigen detection test, as there is for histoplasmosis. Approximately 5% of patients develop chronic pulmonary lesions, including

**FIGURE 80-2** Chronic pulmonary coccidioidomycosis before (*left*) and after (*right*) treatment with ketoconazole.

thin-walled residual cavities, nodules, abscesses, or infiltrates, which may wax and wane. The course and rate of evolution from primary disease are highly variable. Pulmonary foci may coalesce into nodules that persist, resolve slowly, or undergo necrosis to form cavities. Cavities may persist for months or even years, may slowly resolve (Fig. 80-2), or may rupture into the pleural space, causing pneumothorax, empyema, or both.<sup>83</sup> Hemoptysis or, rarely, severe hemorrhage may also occur. In a case-control study conducted in Kern County, California, risk factors for severe pulmonary disease were diabetes, recent history of smoking, low income, and older age.<sup>84</sup>

Dissemination, when it occurs, often presents within a few months of the primary infection. Pregnancy, particularly the third trimester, poses a hazard for dissemination.<sup>85</sup> Filipinos, African Americans, and Hispanics are also at increased risk of dissemination (Fig. 80-3). Patients with poorly developed cell-mediated immune response may have miliary pulmonary infiltrates and widespread extrapulmonary infection with abscesses draining purulent material and many spherules, neutrophils, and few lymphocytes seen in the lesions. This disseminated infection is associated with a negative skin test and high complement fixation antibody titer. In contrast, the patient with partially competent cell-mediated immunity may have a few granulomas in the skin or scattered lung foci, with a few spherules seen trapped within multinucleated giant cells. In patients with AIDS, the infection has a more aggressive course, which correlates inversely with the CD4 lymphocyte count.<sup>78</sup> Focal pulmonary lesions are the most easily treated, whereas diffuse pulmonary disease occurs in those with the lowest CD4 counts and has the shortest survival time—a median of 1 month. Pulmonary cavitation is

rather uncommon in patients with AIDS and coccidioidomycosis.<sup>86</sup> For HIV patients on HAART, one may anticipate a much more benign course, but few data are available.

Coccidioidal meningitis is a chronic lymphocytic meningitis, with low glucose, elevated protein, and culture-positive cerebrospinal fluid (CSF) in up to half of patients.<sup>87</sup>

**FIGURE 80-3** Facial lesions of chronic coccidioidomycosis (arrows).

**FIGURE 80-4** Dissemination of coccidioidomycosis to the bones, resulting in destruction of the L4–L5 vertebrae.

Eosinophilia may occur in the CSF of up to 70% of patients with coccidioidal meningitis.<sup>88</sup> There is associated focal vasculitis, but some series report remarkably few clinically apparent focal lesions. In one series of 15 patients autopsied with disseminated disease, 8 had CNS involvement. Of these, 8 had meningitis, 7 had encephalitis, 5 had parenchymal abscesses and granulomas, 4 had endarteritis obliterans, 2 had infarcts, and 1 had radiculitis. Associated clinical findings included headache, confusion, seizures, and nuchal rigidity, each in a minority of patients; none had focal neurologic findings.<sup>89</sup> A larger series of 25 patients, collected from 1955 through 1958, identified headache, vomiting, and meningismus in multiple patients, but none had focal neurologic deficits. Fourteen died within 8 months of diagnosis, and 4 survived (with no treatment) for more than 55 months.<sup>90</sup> Other series of patients with coccidioidal CNS infection reported clinical consequences of focal vasculitis and recommended that corticosteroids be considered as emergency therapy.<sup>91</sup> Banuelos and coworkers<sup>92</sup> reported 6 patients with brain abscesses. Approximately one-third of patients with brain abscesses have no associated meningitis, and these patients may have negative CSF serology, thus increasing the difficulty of making a diagnosis.

Dissemination to the bones occurs most often in the vertebrae and other weight-bearing joints, such as the knee (Fig. 80-4). Arthritis is associated with synovial thickening and fluid accumulation. Paraspinal abscesses may occur. If the infection is untreated, the course is quite variable and may wax and wane over many years. On the other hand, coccidioidal meningitis is usually lethal within 1 year if not treated.

## DIAGNOSIS

Serodiagnosis is a major indirect method for diagnosis. Acute primary coccidioidomycosis is associated with positive IgM primary tube precipitin [or immunodiffusion tube precipitin (IDTP)] tests. This test is not titrated and usually reverts to negative within a few months of infection. The complement fixation [or immunodiffusion complement fixation (IDCF)] test measures IgG antibody, converts to positive later than the IDTP test, and generally remains positive for months. Rising titers are associated with progressive disease, whereas declining titers are

associated with resolution.<sup>93</sup> In the CSF a positive IDCF of any titer is considered diagnostic of coccidioidal meningitis. ELISA tests are replacing these older procedures. The polymerase chain reaction has been advocated for early diagnosis (prior to serologic conversion) using serum or CSF as the specimen. However, this method is not sufficiently sensitive to be useful in clinical practice.<sup>94</sup> Skin test antigens are not available.

The most specific methods to document coccidioidomycosis are culture or histopathologic evaluation. Bronchial lavage and pulmonary biopsy may be diagnostic when routine sputum cultures are nonrevealing.<sup>95</sup> Needle biopsy of lung nodules may also yield the diagnosis.<sup>96</sup> Tissue biopsies showing the characteristic spherule (Fig. 80-5) are pathognomonic. Mycelial forms of *Coccidioides* may also occur in cytologic and histologic specimens.<sup>97</sup> Obtaining positive cultures of *C. immitis* from clinical specimens is usually not difficult. The organism converts to the mycelial form and grows readily on most culture media, appearing within 7 to 10 days. Recovery of organisms from the CSF is less predictable, although McGinnis<sup>98</sup> has noted that 76% of cases have positive cultures and 8% may have spherules identified. The mold may not produce characteristic arthroconidia for some time. Careless handling of cultures has caused a number of human infections in laboratory workers. *Coccidioides immitis* was declared a “select agent” due to concerns about its use in bioterrorism. The scientific basis for this classification is probably unwarranted.<sup>99</sup> Nevertheless, cultures

**FIGURE 80-5** *Coccidioides immitis* spherule in skin lesion. Note large size of the spherule (arrow), double wall, and inner contents (endospores).

must be handled expeditiously, the organism must be destroyed following identification, and reports must be generated and promptly sent to the appropriate state authorities.

## TREATMENT AND PROGNOSIS

*Coccidioides immitis* has one remarkable distinction from most other fungal pathogens. This organism tests susceptible in vitro to most antifungals. However, clinical responses are often very slow, incomplete, or nonexistent. Relapses occur (sometimes after years of remission) in approximately 30% of patients after treatment with antifungal agents is stopped. Therefore, terms such as “remission” and “disease-free interval,” rather than “cure,” should be used with regard to treatment results for coccidioidomycosis.

Practice guidelines for the treatment of coccidioidomycosis were published in 2000.<sup>100</sup> Approximately half of exposed people remain asymptomatic. The management of patients with primary pulmonary disease is uncertain. For most immunocompetent people, the disease will resolve without antifungals. Patients with concurrent risk factors (immunosuppression, pregnancy in the third trimester, or immediate postpartum status) should be treated. Nonpregnant patients with primary infection with *C. immitis* are treated with itraconazole or fluconazole (400 mg/day) orally for several months. There are no controlled studies, and efficacy is unclear. Amphotericin B is reserved for seriously ill patients with diffuse pneumonia and pregnant patients (in whom the azoles may be teratogenic for the fetus). Amphotericin B has a 50% to 75% response rate. People of Filipino or African American descent have a higher risk for dissemination, and this factor should be considered in the decision to treat.<sup>100</sup>

Ketoconazole produces less than a 40% response rate, as assessed using a global point-counting system developed by the Mycoses Study Group. Better responses are obtained with itraconazole at 400 mg/day (57%) and fluconazole (65%), given at 400 mg/day, for up to 2 years.<sup>101,102</sup> A study comparing oral fluconazole (400 mg per day) versus itraconazole (200 mg twice a day) in the treatment of nonmeningeal coccidioidomycosis found equivalency; however, there was a trend toward greater efficacy with itraconazole. Furthermore, itraconazole showed superior efficacy in skeletal infections.<sup>103</sup> Treatment of coccidioid vertebral disease usually requires surgical stabilization in addition to medical therapy. In all patients with invasive disease, the treatment of coccidioidomycosis should be prolonged, perhaps for several years. Fluconazole relapse rates (37%) are higher than those for itraconazole (16%).

The potent triazoles, voriconazole and posaconazole, have been used to treat coccidioidomycosis. In a murine model of coccidioidomycosis, posaconazole was more effective than itraconazole.<sup>104</sup> Although numbers of patients are limited, responses have been excellent with posaconazole, even in patients failing other antifungals.<sup>105</sup> Posaconazole has the potential of becoming a first-line drug for the treatment of coccidioidomycosis. Caspofungin has proven effective in mice,<sup>106</sup> and there is emerging a very small clinical experience with the drug. However, no general conclusions can be made regarding the efficacy of the echinocandins in the treatment of coccidioidomycosis.

For patients with disseminated coccidioidomycosis, high-dose fluconazole is recommended.<sup>100</sup> Coccidioidal meningitis used to be considered the worst form of coccidioidomycosis,

with only 40% to 50% response rate to intrathecal amphotericin B in follow-up evaluations continued for many years.<sup>87</sup> Recently, fluconazole has proved to be a more effective and well-tolerated treatment for coccidioidal meningitis, with favorable responses in 79% in a Mycoses Study Group investigation of 47 patients.<sup>107</sup> Also in this series, 9 patients had AIDS, of whom 6 achieved a clinical response and survived 9 to 26 months, ultimately succumbing to other causes. Thus, coccidioidal meningitis responds similarly to fluconazole in the presence or absence of AIDS. In this series, symptoms responded more rapidly than resolution of CSF abnormalities, being largely resolved by 4 months of therapy; however, 9 patients had more than 10 leukocytes per microliter in CSF after 20 months of treatment. Responses were similar in patients treated for the first time and in patients who had relapsed after prior therapy. Ten patients failed to respond to 400 mg/day of fluconazole, and some investigators have recommended doses up to 800 mg/day. Fluconazole, with a loading dose of 800 mg/day for several days, followed by fluconazole at 400 mg/day, is the current regimen of choice for coccidioidal meningitis. Itraconazole has also been used for treatment of coccidioidal meningitis, but the experience is limited.<sup>108</sup> In a rabbit model of coccidioidal meningitis, fluconazole and itraconazole had equal efficacies, but fluconazole led to more rapid responses. Neither drug was able to eliminate the fungus from CNS tissues.<sup>109</sup> Whether in AIDS or immunocompetent patients, once azole therapy has been initiated for coccidioidal meningitis, it should be continued lifelong. In a review of 18 patients, 14 patients treated for up to 8 years relapsed when treatment was stopped.<sup>110</sup>

Intravenous amphotericin B is not effective in coccidioidal meningitis, and intrathecal amphotericin B has been given by multiple methods, including Ommaya reservoirs.<sup>111</sup> Intrathecal amphotericin was previously the treatment of choice for coccidioidal meningitis, but should now be reserved for those who fail aggressive azole therapy. In some patients, doses up to 1.5 mg of amphotericin B were administered intrathecally (with hydrocortisone or methylprednisone) with a goal to administer 12 mg/month for 2 months.<sup>112</sup> Treatment averaged 45 months in these patients. Although effective in many patients, response rates were never much higher than 50% despite treatment for years, and complications of intrathecal amphotericin B were many, related to both inflammation caused by the drug and secondary infections caused by the injections.<sup>113</sup>

In AIDS, coccidioidomycosis typically presents toward the later phases of immunodeficiency. Diffuse pulmonary disease is common and is the worst manifestation, with a median survival of only 1 month, and no clearly superior treatment regimens have been identified. Meningitis and focal pulmonary disease are associated with a higher CD4 count and also with better responses to therapy.<sup>78</sup> Posaconazole has been used successfully in patients with AIDS.<sup>105</sup> With HAART, there is the potential of discontinuing chronic suppression when the CD4 counts have risen and the viral load has declined. However, there are no specific recommendations, and any discontinuation should be approached with caution.

## PREVENTION AND CONTROL

There is no effective vaccine or other preventive measure. A vaccine consisting of formalin-killed spherules was tested in

a large study in the San Joaquin Valley in California.<sup>114</sup> Although the vaccine caused seroconversion in 17% of recipients vs. 1% of placebo recipients, there were no differences in the incidence of suspected cases among vaccine recipients and placebo recipients. There are ongoing preclinical studies of coccidioidal vaccines prepared from specific antigens.<sup>115</sup> Using an expression library immunization approach, a protective antigen termed ELI-Ag1 was discovered that protects mice from lethal challenge with *C. immitis* arthroconidia.<sup>116</sup> Studies have suggested that immunization with a potential vaccine against coccidioidomycosis in endemic areas would be cost-effective.<sup>117</sup> Guidelines have been published for field workers in endemic areas to decrease their risk of acquiring coccidioidomycosis.<sup>72</sup>

## ■ Cryptococcosis

### AGENT

*Cryptococcus neoformans* is the only encapsulated fungus, appears as spherical or ellipsoid yeast-like cells, reproduces by budding, and is ubiquitous in soil and avian guano.<sup>118</sup> The organism can transform to a mycelial form (*Filobasidiella neoformans*) and mate sexually.<sup>119</sup> There are two subspecies, *C. neoformans* var. *neoformans* and *C. neoformans* var. *gattii*. Five serotypes of *C. neoformans*, A through D and AD, have been recognized based on the antigenic specificity of the capsule.<sup>120</sup> *C. neoformans* var. *neoformans* (serotypes A and D) has a worldwide distribution and can infect both immunocompetent and immunodeficient subjects. Serotype A is the cause of most cases of cryptococcosis in patients with AIDS. *C. neoformans* var. *gattii* (serotypes B and C) is found as a mycelium on *Eucalyptus camaldulensis*, a tree native to Australia, where it causes severe pneumonia and meningitis in immunocompetent patients; it is less commonly seen in AIDS patients. Cryptococcosis caused by *C. neoformans* var. *gattii* has also been reported from areas in which *E. camaldulensis* trees have been imported.<sup>121</sup> Other tree species have been found that also harbor *C. neoformans* var. *gattii*.<sup>122</sup> The varietal status of serotype AD is uncertain.<sup>120</sup>

### EPIDEMIOLOGY

The incidence of cryptococcosis has increased in many areas corresponding with the pandemic of AIDS and is a major cause of morbidity and mortality among these patients.<sup>123</sup> India, with its burgeoning AIDS epidemic, has seen a sizeable increase in the number of cases of cryptococcosis.<sup>124</sup> In both Rwanda and Cambodia, *Cryptococcus* is the leading cause of meningitis in people with AIDS.<sup>125,126</sup> In developing countries without access to antifungal drugs and HAART, cryptococcal meningitis is often rapidly fatal. In a cohort of AIDS patients from Uganda, cryptococcosis accounted for 17% of the mortality, with a median survival of only 26 days after diagnosis.<sup>127</sup> In a study from Zimbabwe conducted in 1995, cryptococcosis was the AIDS-defining illness in 88% of AIDS patients admitted to two tertiary care hospitals; the median survival from time of diagnosis was 14 days.<sup>128</sup>

In Brazil, cryptococcosis is a significant problem in the AIDS population as well.<sup>129</sup> Fortunately, the incidence of

cryptococcosis has diminished by greater than 80% since the advent of HAART in the United States and Europe. Furthermore, in the HAART era patients tend to present with cryptococcosis as the first manifestation of an opportunistic infection, whereas in prior years it was one of many such infections throughout the course of AIDS.<sup>130</sup> Cryptococcosis remains a major threat to life in developing nations, where access to HAART is limited. Cryptococcosis also occurs in people with other conditions causing defects in cell-mediated immunity, such as lymphoma, chronic leukemia, organ transplant, cirrhosis of the liver, and chronic steroid use.

### DISEASE AND PATHOGENESIS AND IMMUNITY

Host defenses, virulence, and inoculum size determine the likelihood of development of clinical disease caused by *C. neoformans*. In the Bronx, New York, serological testing indicates that the majority of children (70%) have been exposed to the fungus, but very few children have symptomatic disease.<sup>131</sup> Depressed cell-mediated immunity is the major risk factor for development of cryptococcosis. Depressed phagocytosis, opsonization, and complement activity are also important contributors.<sup>132</sup> Anticryptococcal antibodies have been shown to be protective in experimentally inoculated animals.<sup>133</sup> An initial small clinical experience has shown that therapeutic monoclonal antibodies are benign, but efficacy has not been tested. Cryptococci are inhaled and, in most people, are contained and killed by neutrophils and alveolar macrophages. In an effective immune response to *C. neoformans*, murine models indicate that IL-12 and IL-18 act synergistically to stimulate early interferon- $\gamma$  production by natural killer cells and  $\gamma\delta$  T cells, which stimulates macrophage destruction of intracellular cryptococci. This effect decreases fungal burdens in the lung and brain.<sup>134</sup> In a murine model of pulmonary and disseminated disease, a Th1-type immune response is necessary to control the infection.<sup>135</sup> Thereby, granulomas form in the lung or brain to control the infection.<sup>120</sup> Humoral immunity also contributes to host defense against *Cryptococcus* by providing opsonins for effective phagocytosis, enhanced natural killer cell function, and clearance of capsular polysaccharides.<sup>120</sup> However, under conditions of defective cell-mediated immunity, there are defective granuloma formation and fewer intracellular yeast, and extracellular fungal masses are present.<sup>120</sup>

The most important virulence factor of *C. neoformans* is its polysaccharide capsule. The principal capsular component, glucuronoxylomannan, displays a number of immunomodulatory activities: reduction of the anticryptococcal activity of neutrophils<sup>136</sup>; induction of IL-10 production by monocytes, which inhibits a Th1-type immune response<sup>137</sup>; and disruption of dendritic cell maturation and activation.<sup>138</sup> *C. neoformans* is able to produce melanin using various phenolic substrates that are found in human brain tissue.<sup>139</sup> The melanin protects the fungus from phagocytosis, nitrogen- and oxygen-derived oxidants, and amphotericin B. Superoxide dismutase and thiol peroxidase also protect the fungus from host-derived oxidants.<sup>140,141</sup> *C. neoformans* also displays phenotypic switching, in which variant colonies are produced that differ in morphology, virulence, and capsular characteristics, which in turn alters the immune response.<sup>142</sup>

**Table 80-2 Clinical Manifestations of Cryptococcosis**

Site	Clinical Findings
Pulmonary	Cough, chest pain, sputum production, fever, nodules, hilar adenopathy, focal or diffuse infiltrates, pleural effusion
Central nervous system	Meningitis: subacute: headache, meningismus, nausea and vomiting, mental changes, photophobia; focal: cryptococcoma
Skin	Acneiform lesions, papules, purpura, vesicles, nodules, ulcers, molluscum-like lesions, cellulitis
Others	Eye, prostate, adrenal, liver, heart, bone, lymph node, joint, kidney

In immunosuppressed patients, the organisms prevail to cause either pneumonia or disseminate to reach the meninges, skin, and bones. Primary cryptococcal pneumonia has been very well described in immunocompetent as well as immunosuppressed people. In immunocompetent hosts, chest infection is usually relatively mild, with productive cough, pleuritic chest pain, and fever as the main manifestations. Chest radiographs show single or multiple lung nodules, mediastinal lymphadenopathy, and occasionally pleural effusion. Dissemination is exceedingly rare.<sup>143</sup> However, in the immunocompromised host, cryptococcal pneumonia is more severe, with prominent alveolar and interstitial infiltrates; moreover, nodules and cavitation can be seen. In these patients, dissemination to the CNS is common, especially in those with AIDS.<sup>144</sup>

Cryptococcal meningitis is the most frequent presentation of cryptococcosis in the immunocompromised host. It occurs almost exclusively in immunocompromised patients. Typically, cryptococcal meningitis is subacute, manifested by progressive headache, fever, lethargy, personality changes, or memory loss. Variable presentations, either acute or chronic, have been described. Signs of meningeal irritation are usually absent.<sup>145</sup> Skin involvement in cryptococcosis is not uncommon, particularly with disseminated disease. A wide variety of skin lesions have been reported, including papules, acneiform rash, cellulitis, abscesses, ulcers, molluscum contagiosum-like lesions, vesicles, and nodules.<sup>145</sup> Bone, eye, and the prostate gland are other sites involved in *C. neoformans* infection. The prostate is a potentially protected sanctuary during treatment, a situation that might result in relapse.<sup>146</sup> Clinical manifestations of cryptococcosis are summarized in Table 80-2.

In contrast, *C. neoformans* var. *gatti* causes disease primarily in immunocompetent people and has increased propensity to form cryptococcomas in the brain and lungs. It produces greater neurologic morbidity and is less responsive to treatment than var. *neoformans*.<sup>147</sup>

## DIAGNOSIS

Demonstration of *C. neoformans* in tissue or normally sterile body fluids, through cultures or special stains, is the basis for the diagnosis of cryptococcosis. GMS stain demonstrates yeast nonspecifically, whereas mucicarmine stain is specific in staining

the capsule. The India ink preparation or nigrosin stain can be rapidly performed and is very useful in demonstrating the encapsulated yeast in tissues and body fluids. *C. neoformans* can be commensal in the mouth and sputum, which makes sputum cultures less useful in the diagnosis of cryptococcal pneumonia. *C. neoformans* grows well in Sabouraud agar and routine laboratory media, with white to cream-colored colonies developing in 36 to 72 hours.

Detection of the capsular polysaccharide antigen is both sensitive and specific. Two methods have been developed with comparable sensitivity and specificity—the latex agglutination test and enzyme immunoassay.<sup>148</sup> These techniques are more sensitive (95%) than India ink preparation (50%) and cultures (75%). Antigen detection is very helpful in promptly detecting relapse. A titer of more than 1:8 is indicative of active disease in the less severely immunosuppressed patient, and if it is detected in the CSF, it makes the diagnosis of cryptococcal meningitis highly likely. Titers in the CSF and serum are commonly greater than 500 in patients with AIDS and cryptococcosis. When cryptococcal meningitis is suspected, lumbar puncture is essential. Opening pressure should be measured, and CSF should be examined by the India ink method, cryptococcal antigen assay, and culture.

## TREATMENT AND PROGNOSIS

Practice guidelines for the treatment of cryptococcosis were published in 2000.<sup>149</sup> In CNS disease in non-HIV patients, an induction/consolidation approach is used; amphotericin B (0.7 to 1 mg/kg/day) combined with 5-flucytosine (5-FC) (25 mg/kg every 6 hours) for 2 weeks, followed by fluconazole (400 mg/day) for 10 weeks, is recommended. Combined treatment with amphotericin and 5-FC clears cryptococci from the CSF faster than amphotericin B alone.<sup>150</sup> Liposomal amphotericin B, which is less toxic than conventional amphotericin B, can be used for treatment of cryptococcal meningitis at doses of 3 to 6 mg/kg/day. Fluconazole and itraconazole are active against *C. neoformans* and can be used to treat pulmonary disease in both HIV and non-HIV patients with mild-to-moderate pulmonary disease; non-HIV patients should be treated for 6 to 12 months, but HIV patients may require life-long therapy, depending on the response to antiretroviral therapy. Severe pulmonary disease in the non-HIV patient should be treated like CNS disease. In HIV patients with CNS disease, a similar induction/consolidation approach can be used as in the non-HIV patient, but after the 10-week period of fluconazole, maintenance therapy with fluconazole at 200 to 400 mg per day is necessary.<sup>149</sup> If fluconazole is used as initial treatment for cryptococcal meningitis, doses of 400 to 800 mg/day are indicated; however, it sterilizes the CSF more slowly than amphotericin B.<sup>151</sup> In cases of AIDS, suppressive therapy with fluconazole (200 mg/day) should be continued until the CD4 count has risen to greater than 100 cells/ $\mu$ L, at which time treatment may be discontinued.<sup>152</sup> Some patients have had months of HAART with CD4 greater than 100 cells/ $\mu$ L, whereas others have stopped relatively soon after the CD4 count reached 100 cells/ $\mu$ L. Four relapses occurred among 100 patients in this setting.

In some patients, rapid rise of CD4 and decline in HIV titers have been associated with increasing headache and signs of meningitis.<sup>153</sup> This may occur as soon as 11 days after

HAART, and it may occur with very little change in total CD4 counts. Typically, the CSF shows an inflammatory response with lymphocytes and a stable or lower antigen concentration. Organisms may be seen on India ink examination, but cultures are negative. This is a form of "immune reconstitution disease." This syndrome is managed by continuing the antifungal drug suppression and often limited courses of corticosteroids to reduce the exuberant host inflammatory response.

In recent years, in vitro resistance to fluconazole (MIC >16 µg/mL) and clinical relapse have been seen with cryptococcal meningitis in AIDS patients.<sup>154</sup> Mutations of the target lanosterol 14- $\alpha$  demethylase may account for clinically relevant resistance.<sup>155</sup> Some resistance to voriconazole has also been noted.<sup>156</sup> For patients with infection with fluconazole-resistant isolates, both voriconazole and posaconazole may be acceptable alternatives. Response to each has been reported in approximately 50% of patients.<sup>157</sup> Nevertheless, in the United States, surveillance through 1998 indicates that resistance of *C. neoformans* to azole antifungal agents is rare.<sup>158</sup> Caspofungin has no role in the management of cryptococcosis because the target 1,3- $\beta$ -D-glucans are not present in *C. neoformans*.

Because increased intracranial pressure (ICP) to more than 25 cm of water has been observed to be associated with acute mortality, it is important to maintain normal ICP by frequent lumbar punctures or CSF shunting if required.<sup>159</sup> In one series of 10 patients shunted, 9 improved.<sup>160</sup> In another series of 27 patients, placement of shunts was not uniformly helpful, with poor outcome in 10, perhaps because of delays in surgery. Coma indicated a poor prognosis.<sup>161</sup>

The prognosis in cryptococcosis is variable, being determined by many factors. Limited disease such as cryptococcal pneumonia carries a better prognosis than disseminated disease with meningitis. The degree of immunosuppression of the host and the effectiveness of antifungal therapy are the main prognostic factors. In non-HIV-associated cases of cryptococcal meningitis, a poor outcome is associated with a high burden of organisms (positive India ink or high CSF or serum cryptococcal antigen concentration), poor inflammatory response (CSF white blood cell count less than 20/ $\mu$ L), low CSF glucose, high CSF opening pressure, and altered mental status.<sup>162</sup> In HIV-infected patients, low serum albumin, low CD4 count, and high CSF antigen titers (>11,024, reflecting heavy fungal burden) are pretreatment indicators that correlate with poor outcome.<sup>163</sup> Likewise, rising CSF antigen titers suggest that the infection is not resolving. In a study of untreated cryptococcal meningitis from Zimbabwe, severely impaired mental status and hyponatremia at presentation were associated with death within 3 days, whereas a low CSF glucose level was associated with survival greater than 14 days.<sup>128</sup>

## PREVENTION AND CONTROL

There are no vaccines for *C. neoformans*. Because the organism is widely distributed in nature, there is no way to prevent contact with *C. neoformans*. No human-to-human transmission is known to occur, except with organ transplantation. Transmission from pet psittacine birds has been reported. Thus, it may be prudent to advise immunocompromised patients to avoid birds and their guano.<sup>164</sup> Studies have shown fluconazole at 200 mg/day to be effective but costly for

primary prophylaxis against cryptococcal meningitis in AIDS patients.<sup>165</sup> A lower dose of 100 mg three times per week may be effective and is less costly.

# Paracoccidioidomycosis

GREGORY M. ANSTEAD  
JOHN R. GRAYBILL

## INTRODUCTION

Paracoccidioidomycosis is a systemic mycotic infection caused by the dimorphic fungus *Paracoccidioides brasiliensis*.<sup>1</sup> *Paracoccidioides brasiliensis* is restricted to the tropical Americas, from Mexico to Argentina. Approximately 80% of cases occur in Brazil, followed by Colombia and Venezuela. There have been virtually no cases reported from the Caribbean islands, Guyana, Suriname, or Chile. Cases are not randomly distributed within each country but are concentrated in areas with abundant forests and waterways, 90 to 180 cm of rainfall per year, short winters, and rainy summers.<sup>2</sup> *Paracoccidioides brasiliensis* has been isolated from the nine-banded armadillo (*Dasypus novemcinctus*). Infected armadillos were found more frequently in areas of disturbed vegetation, in artificial eucalyptus or pine forests, at altitudes below 800 m, near water sources, and in areas with sandy, acidic soil.<sup>3</sup>

## AGENT

The free-living form of the fungus is presumed to be the mycelium. The mold can be grown at 18°C to 26°C, and it forms white to tan colonies with short mycelia. Hyphae are thin, septate, and generate pedunculated or single-cell arthroconidia that bud off the mycelium. When conidia are cultured in rich media at 37°C, they convert to and multiply as yeast-like cells. The cells vary from 4 to 30 µm in size and give rise to multiple narrow-based, elongated daughter cells budding from the “mother” cell. This gives a characteristic “Mickey Mouse” or “pilot wheel” appearance, similar to that seen in tissue biopsies (Fig. 81-1). *Paracoccidioides brasiliensis* is quite hardy and can multiply at 4°C in water.<sup>2</sup>

## EPIDEMIOLOGY

All of the few cases reported outside of the endemic area occurred in patients who had traveled within the endemic regions. In these cases, the mean latency period between exposure and disease was 15 years, indicating that the fungus undergoes a characteristic long dormancy before producing the disease.<sup>1,2</sup> Because of the long latency, and because there have been no epidemics, the natural habitat of the fungus

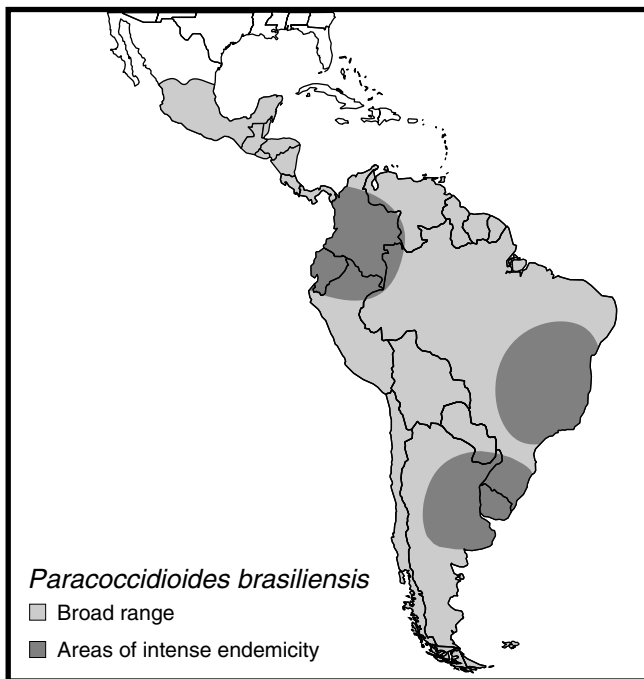

**FIGURE 81-1** Gomori's methenamine silver stain of *Paracoccidioides brasiliensis* in tissue biopsy.

is unclear. Male rural workers, particularly woodcutters, are at highest risk. There are occasional cases in children (3%) and young adults (10%), but most commonly, patients are between 20 and 40 years old.<sup>1</sup> The rural predominance may be one reason why paracoccidioidomycosis has rarely been reported in patients with acquired immunodeficiency syndrome (AIDS).

## DISEASE

Paracoccidioidomycosis takes one of two forms: the acute (juvenile) disease or the adult chronic form.<sup>1</sup> Unlike the adult form, the juvenile form, which occurs primarily in children and adolescents, has no gender predilection. Juvenile paracoccidioidomycosis reflects only 3% to 5% of cases and is characterized by blood-borne dissemination to multiple sites, predominantly in the reticuloendothelial system (spleen, liver, lymph nodes, lungs, and bone marrow). Pneumonia, lymphadenopathy, hepatosplenomegaly, mucosal and skin ulceration, adrenal insufficiency, and cachexia all mark this form of the disease. Many replicating fungal cells are seen, with little granuloma formation and no fibrosis. Lymphadenopathy and hepatosplenomegaly may suggest lymphoma rather than infection. Mesenteric adenopathy may cause bowel obstruction. Central nervous system (CNS) involvement has been described.<sup>4</sup> In a series of 173 cases of paracoccidioidomycosis, 13.9% had CNS involvement, typically revealed as multiple

hypodense lesions with annular or nodular enhancement in the cerebral hemispheres; meningitis and spinal cord involvement are much less common. In this series, seizures were the most frequent neurologic presentation.<sup>4</sup> Chronic meningitis is also a common neurologic manifestation.<sup>5</sup> If the disease is untreated, mortality is high.

In contrast, the adult form of the disease occurs usually in males, progresses over months to years, and represents more than 90% of cases. Progressive pulmonary lesions are the hallmark, and in 25% of patients the lungs are the only organ involved. Symptoms are nonspecific and include cough, sputum production, weight loss, and dyspnea. In other patients, lymphadenopathy, hepatosplenomegaly, or skin and mucosal ulcerations may prompt the patient to seek medical attention (Fig. 81-2; Table 81-1; see also Plate 126-2E). Gallium scanning may reveal clinically unsuspected foci.<sup>6</sup> Chest radiographs typically show dense bilateral nodular, fibrotic, and cavitary lesions. The lesions may appear quite similar to those of tuberculosis, except for the propensity to involve the central or basilar lung fields and to spare the apices.<sup>1</sup> The process is destructive, and the nodular lesions may be associated with caseation and dense fibrosis.<sup>1</sup> Pulmonary function abnormalities may be relatively mild compared with the radiographic findings and are usually obstructive. With healing, chronic dyspnea, dysphonia, microstomia, glottic and tracheal stenosis, and adrenal insufficiency may occur. Healing occurs in association with dense fibrosis of affected tissues, and in some cases fibrosis may lead to cor pulmonale.<sup>7</sup> Despite efficacious therapy with azole antifungal agents, the fibrotic sequelae persist.<sup>8,9</sup>

In recent years, paracoccidioidomycosis has been recognized as an AIDS-associated opportunistic infection.<sup>10,11</sup> A review in 1995 included only 27 reported cases. This form of disease resembles the juvenile acute form and presents with aggressive pulmonary and widespread disseminated

**FIGURE 81-2** Ulcerative lesion on the neck of a patient with paracoccidioidomycosis (arrow). (Courtesy of Dr. Angela Restrepo, CIB, Medellin, Colombia.)

disease (see Table 81-1). Meningeal involvement is more common in the AIDS patient, compared with less than 5% incidence in a series of non-AIDS patients.<sup>1</sup> It is of interest that AIDS-associated histoplasmosis is much more common than paracoccidioidomycosis. The reasons for this are unclear

**Table 81-1 Organ Involvement in Paracoccidioidomycosis**

Organ	Nonimmuno-compromised Patients (n = 352)	Patients with AIDS (n = 27)
Lungs	77%	63%
Mucous membranes	63%	15%
Skin	12%	48%
Lymph nodes	13%	37%
Spleen, liver	5%	19%
Adrenals	3%	4%
Other	2%	15% (including 2 central nervous system, 1 bone marrow, and 1 blood)

From Brummer E, Castañeda E, Restrepo A: Paracoccidioidomycosis: An update. Clin Microbiol Rev 6:89–117, 1993.

and may relate to less contact of rural people with the human immunodeficiency virus (HIV) or the use of trimethoprim-sulfamethoxazole (which is effective against *P. brasiliensis*) as prophylaxis against *Pneumocystis*. In the series of Goldani and Sugar,<sup>10</sup> 12 of 13 patients with AIDS and paracoccidioidomycosis had not received trimethoprim-sulfamethoxazole prophylaxis for pneumocystosis.

## **PATHOGENESIS AND IMMUNITY**

The pathogenesis, although not precisely defined, probably follows inhalation of conidia and subsequent transformation of the conidia into yeast cells within alveolar macrophages.<sup>1</sup> In the majority of immunocompetent patients, fungal growth is halted in these initial foci, and the infection is subclinical. Some patients become symptomatic years after they leave the endemic area. Therefore, some yeast cells must persist after the initial infection and reactivate later in more permissive circumstances. Markers of virulence are not well defined. Older cultures are less virulent in mice than are recent clinical isolates.<sup>12</sup> Mammalian female sex hormones, such as estradiol, alter mycelial band patterns and block synthesis of proteins needed for transformation to the yeast phase.<sup>13</sup> In vitro studies clearly show that estradiol inhibits transformation from the mycelium to the yeast. Estrogen binding proteins have been found in cytosol of both conidia and yeast cells. If estradiol is added to mycelium before the temperature is raised, novel proteins are produced. However, in vivo studies in rats found that females were highly susceptible to infection; castration, which should lower hormones and increase susceptibility, actually reduced it.<sup>14</sup> However, these studies were done with yeast cells, which are less susceptible than conidia<sup>13</sup> to hormone influences in vitro. In another study that used inhaled conidia as the infecting inoculum, in normal male mice there was progressive transformation of the conidia into tissue-form yeast cells in the first 96 hours of infection, whereas in the normal female mice no conidia transformation occurred.<sup>15</sup>

The role of estradiol in altering the pathogenesis of paracoccidioidomycosis was definitively demonstrated in a study by Aristizabal and colleagues.<sup>16</sup> In this experiment, using inhaled conidia as the infecting inoculum, normal male mice suffered progressive disease, whereas normal females resisted disease progression. Castrated male mice that received exogenous estradiol initially resisted disease but ultimately had disease progression. Castrated female mice treated with testosterone were unable to control the infection.<sup>16</sup> Thus, estradiol inhibits transformation of the mycelia to the yeast form and promotes resistance to disease progression.

Skin tests from healthy subjects in endemic areas do not show male predominance, and male cases do not predominate among children. This situation again suggests that female sex hormones are active in suppressing symptomatic disease in women but have no influence on primary infection. Skin tests have not been useful in delineating hyperendemic areas where the fungus could be identified in its natural ecological niche.<sup>17</sup> The juvenile form can be reproduced in athymic mice and is relatively common in the few AIDS patients who have been reported to have paracoccidioidomycosis.<sup>10,11</sup> Competent cell-mediated immunity is thought to be the key to recovery.<sup>1,2,5,18,19</sup>

## **DIAGNOSIS**

The endemic zone of paracoccidioidomycosis overlaps that of histoplasmosis in South America, and both the juvenile forms and the chronic pulmonary and disseminated forms of these two fungal diseases are quite similar. Therefore, a major diagnostic consideration in these areas of geographic overlap is histoplasmosis versus paracoccidioidomycosis because the diseases may be treated with different agents. Hepatosplenomegaly and bone marrow involvement are more prominent in disseminated histoplasmosis. Mucocutaneous lesions and adrenal insufficiency may occur in both diseases. In addition, approximately 10% of patients with paracoccidioidomycosis have coexistent tuberculosis, so this potential copathogen must be evaluated in each patient.<sup>2</sup>

On histopathologic stains of tissue biopsies, the fungal elements are pathognomonic. Potassium hydroxide preparations or calcofluor stain of sputum may also show thick-walled mother cells with multiple narrow-based budding daughter cells. Methenamine silver stain of sputum may be more sensitive than the KOH preparation. A mixed pyogranulomatous host response with neutrophils, mononuclear cells, and macrophages is usually present. Culture on Sabouraud agar at room temperature yields slowly growing (20 to 30 days) mycelia with the appearance of "white mouse hair." The identity can be confirmed by subculture at 37°C, with conversion to the more rapidly growing yeast form.

The complement fixation test has been used since 1916 for the diagnosis of paracoccidioidomycosis. Approximately 90% of patients have specific antibodies demonstrable by complement fixation, latex agglutination, immunofluorescence, tube precipitation, enzyme-linked immunosorbent assay, or other methods. Immunoblotting has been described as a highly sensitive method for the diagnosis of paracoccidioidomycosis.<sup>20</sup> When multiple tests are done on the same patients, results may be conflicting, and Restrepo<sup>21</sup> advises using only one test and using it consistently. IgG antibodies are elevated during the first year after infection but may be absent in patients with severe immunosuppression, such as AIDS.<sup>2</sup> In patients with progressive disease and depressed cell-mediated immunity, IgE antibodies rise later. Tests vary among different manufacturers, and there may be extensive cross-reaction of some antibodies with *Candida*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, or other fungal pathogens. Therefore, a positive serologic test does not in itself confirm active paracoccidioidomycosis.<sup>1</sup> Antigenemia has been detected in patients with paracoccidioidomycosis and offers a diagnostic alternative in those with severe immunodeficiencies. However, there may be false-positive reactions in patients with other mycoses.<sup>22</sup> Skin testing with paracoccidioidin may be useful epidemiologically, and in the individual patient it may be helpful in that conversion from anergy to a positive reaction is associated with a good prognosis.

## **TREATMENT AND PROGNOSIS**

Paracoccidioidomycosis is one of the first major mycoses for which effective treatment became available; in 1940, Ribeiro found sulfonamide to be effective. Sulfadiazine (6 g/day) and trimethoprim-sulfamethoxazole, because of low cost, are still the mainstay of treatment. Because of the high relapse rate (as high as 25%), it is necessary to continue treatment with

sulfonamides for as long as 5 years or at least 1 year after antibody titers have resolved or stabilized at a low titer.<sup>1,2</sup> Amphotericin B is beneficial, but the indications are not clear. Absence of symptoms for 2 years after cessation of therapy is considered by some to represent a clinical cure.<sup>1</sup> Three mycologically negative specimens are also considered by some to represent a cure.<sup>1</sup> Relapses may occur in as many as 38% of patients<sup>2</sup> and may be preceded by a rise in antibody titers.<sup>1</sup> Ketoconazole, at 200 mg/day, has been recommended for 6 to 12 months and, with 92% responses and 11% relapses, is more efficacious than sulfonamides.<sup>23</sup> Fluconazole is also effective, but high doses of 400 mg/day may be required.<sup>24</sup> The drug of choice is itraconazole (100 mg/day) for only 3 to 6 months, with 95% responses and 3.5% relapses.<sup>25</sup> Currently, the greatest unresolved problem with therapy is prevention of the severe fibrosis that accompanies healing, no matter what therapeutic agent is used.

Patients with AIDS have severe disseminated disease. Treatment is complex and in a review included multiple and serial drug regimens.<sup>10</sup> Of 27 patients, 21 (78%) were treated. Of the 15 patients who received a sulfonamide preparation, 10 survived, 3 died, and the outcome was unknown in 3 other patients. Of the 11 who received amphotericin B, 5 survived and 6 died. Of the 10 who received ketoconazole, 5 survived, 4 died, and the outcome was unknown in 1 patient. One cannot use such data to attribute drug efficacy because the patients were not similarly ill, patients clearly received multiple drugs, and those who were more seriously ill or who failed other drugs were given amphotericin B. Overall mortality was 30% of the 21 patients to whom specific antifungal therapy was given. This fatality rate is much higher than that for non-AIDS patients. When disease responds to initial treatment, lifelong suppressive therapy may be required, preferably using an azole antifungal. Histoplasmosis and cryptococcosis tend to remain in remission when treatment is discontinued in patients who have responded well to highly active antiretroviral therapy (HAART) with a sustained rise in CD4 T cells. Perhaps in the future this will be documented as well for paracoccidioidomycosis.

For additional information on paracoccidioidomycosis, the readers are referred to Restrepo-Moreno.<sup>5</sup>

# Penicilliosis Marneffei

GREGORY M. ANSTEAD  
JOHN R. GRAYBILL

## INTRODUCTION

*Penicillium* species are fungi widely distributed in nature, found mainly in the soil and decomposing organic matter, and are considered to be common laboratory culture contaminants. *Penicillium marneffei* is by far the species that most commonly causes human disease. It was first reported as an animal pathogen in the bamboo rat *Rhizomys sinensis* in Vietnam by Capponi and associates in 1956.<sup>1</sup> Segretain<sup>2</sup> described the fungus and in 1959 named it in honor of Dr. Marneffe, the director of the Pasteur Institute of Indochina. Segretain was the first to note acquisition of the infection after accidental inoculation of his finger, which caused a local infection that resolved spontaneously. The first naturally occurring infection

was reported by DiSalvo and colleagues<sup>3</sup> in 1973 in an American with Hodgkin's lymphoma who had traveled to Southeast Asia. The second human infection was not reported until 1984.<sup>4</sup> Since then, an increasing number of reports have been published. In recent years, there has been an enormous increase in the incidence of this infection in endemic areas, corresponding to the increase in acquired immunodeficiency syndrome (AIDS) cases.<sup>5</sup> The first case of penicilliosis marneffei in a patient with AIDS was reported in 1988.<sup>6</sup> Currently, penicilliosis marneffei is the fourth most common opportunistic infection, after tuberculosis, pneumocystosis, and cryptococcosis, in AIDS patients in Thailand.<sup>7,8</sup>

## AGENT

*Penicillium marneffei* is the only species of the genus *Penicillium* known to be thermally dimorphic, growing in mycelial form at 25°C and in yeastlike form at 37°C and dividing by binary fission. The dimorphism of this fungus has been proposed as a factor in its greater pathogenicity compared to other members of the genus *Penicillium*.<sup>9</sup>

## EPIDEMIOLOGY

All cases are from Southeast Asia (Thailand, Vietnam, Myanmar, Hong Kong, Indonesia, Laos, Malaysia, Singapore, Taiwan, the Manipur state of India, and the Guangxi province of China) or in people who traveled to these areas.<sup>5,10,11</sup> The natural reservoir of the fungus has not been identified. The organism has been isolated from the viscera of four species of bamboo rats and from the soil in areas where the rats live; the excrement of these fossorial rats may promote the growth of the fungus.<sup>12</sup>

*Penicillium marneffei*

■ *Penicillium marneffei*

**Table 82-1 Clinical Features of 80 Human Immunodeficiency Virus–Infected Patients with Disseminated *Penicillium marneffeii* Infection**

Symptoms and Signs	No. (%)
Fever	74 (93)
Skin lesions	54 (68)
Cough	39 (49)
Diarrhea	25 (31)
Temperature >38.3°C	79 (99)
Weight loss	61 (76)
Anemia	62 (78)
Jaundice	6 (8)
Generalized lymphadenopathy	46 (58)
Hepatomegaly	41 (51)
Splenomegaly	13 (16)
Skin lesions	57 (71)
Genital ulcer	5 (6)

Modified from Supparatpinyo K, Khamwan C, Baosoung V, et al: Disseminated *Penicillium marneffeii* infection in Southeast Asia. *Lancet* 344:110, 1994.

The main risk factor for infection is occupational soil exposure during the rainy season. Contact with or consumption of the bamboo rats does not appear to be a risk factor.<sup>13</sup>

## DISEASE

Clinical manifestations of penicilliosis marneffeii are non-specific. They usually develop over weeks but may be more acute, manifested by fever, chills, prostration, weight loss, and anemia. Reticuloendothelial involvement presents as generalized lymphadenopathy and hepatomegaly (Table 82-1). Liver injury may be manifested by high transaminases and alkaline phosphatase, and the blood leukocyte count is variable.

In the HIV-infected patient, there frequently are diffuse papular skin lesions with central necrosis or umbilication resembling *molluscum contagiosum*<sup>7,14</sup> (Fig. 82-1). Other

**FIGURE 82-1** Molluscum contagiosum–like lesions in a patient with penicilliosis marneffeii. (From Supparatpinyo K, Khamwan C, Baosoung V, et al: Disseminated *Penicillium marneffeii* infection in Southeast Asia. *Lancet* 344:110, 1994.)

cutaneous signs include maculopapular rash, pustules, and subcutaneous nodules. Mucocutaneous ulcers, including genital sites, can be chronic and recurrent. Respiratory complaints include cough and dyspnea. Chest radiographic findings include diffuse reticulonodular, localized interstitial, or alveolar infiltrates. One case of upper airway obstruction due to retropharyngeal abscess has been reported.<sup>15</sup> Osteolytic bone lesions, usually multiple, have been described. Arthritis can be monoarticular or polyarticular, with no specific joint predominance.<sup>16</sup> Clinical evidence of central nervous system involvement is rare. The differential diagnosis of penicilliosis marneffeii includes tuberculosis, histoplasmosis, cryptococcosis, *Mycobacterium avium*–*intracellulare* complex infection, and lymphoid malignancies.

## PATHOGENESIS AND IMMUNITY

The pathogenesis of penicilliosis marneffeii has been poorly studied. Although the disease can be localized, it is more likely to be disseminated in both normal and immunocompromised hosts. Infection is thought to occur through inhalation of the spores or possibly through cutaneous inoculation. The organisms are engulfed by macrophages, in which they multiply intracellularly and transform into yeasts. Dissemination of infection occurs through the lymphatics or hematogenously. The reticuloendothelial system is predominantly involved. The infection can remain dormant and reactivate later, as evidenced by patients having the disease years after leaving the endemic area. In the immunocompetent host, the cell-mediated immune response is prominent with the formation of epithelioid granulomas that are indistinguishable from tuberculous granulomas.<sup>10</sup> In a murine model of infection, wild-type mice controlled the infection with granuloma formation and the elaboration of a classic Th1 immune response (high levels of interferon- $\gamma$  and interleukin-12). Conversely, interferon- $\gamma$  knockout mice suffered rapid death; the spleen and liver showed abundant yeast forms and an absence of granuloma formation.<sup>17</sup> There is no evidence for a role of humoral immunity in the resolution of penicilliosis marneffeii infection. A suppurative reaction has been described rarely in immunocompetent patients.<sup>10</sup> In patients with HIV infection, the histopathologic features depend on the degree of immunosuppression.<sup>18</sup> At lower CD4 cell counts, the disease tends to be more invasive, with a blunted immune response reflected by the absence of granulomas and extensive proliferation of extracellular yeast and intracellular forms within foamy macrophages. Yeast forms can occasionally be demonstrated in peripheral blood.<sup>18,19</sup>

## DIAGNOSIS

A history of travel or residence in the endemic region is essential information to facilitate a diagnosis. In disseminated disease, microbiologic diagnosis through cultures of the organism from several body sites has been highly sensitive, approaching 100% from bone marrow and lymph nodes. In HIV patients infected with *P. marneffeii*, the organism has been recovered from blood cultures in 76% of cases.<sup>7</sup> Other sites that have yielded positive cultures include skin, liver, bone, joints, lung, and occasionally urine. Sabouraud dextrose agar is the culture medium of choice. The fungus grows rapidly

**FIGURE 82-2** A, Small budding yeast of *Histoplasma capsulatum* (arrow). B, Larger elongated yeastlike form of *Penicillium marneffei* with central septum (arrow).

within 2 to 5 days in its mycelial form, producing gray colonies and a characteristic red pigment that diffuses throughout the agar.

Pathologic diagnosis can be more difficult in immuno-competent patients in whom granulomatous inflammation may be the only finding, with negative fungal stains. In immunosuppressed patients (mainly with HIV), there is more extensive disease, and numerous organisms are demonstrated by Gomori's methenamine silver or periodic acid–Schiff stains.<sup>5,7</sup> Wright-stained specimens from skin lesions, bone marrow, or, occasionally, peripheral blood may show yeast cells.<sup>11,20</sup> *Penicillium marneffei* bears a morphologic resemblance to *Histoplasma capsulatum*, and it can be difficult to distinguish between them. However, *P. marneffei* tends to form more elongated yeast cells with no budding and divides by central septate fission rather than budding (Fig. 82-2).

Specific fluorescent antibody examination of tissue samples has been described.<sup>21</sup> A few serodiagnostic techniques have been described, including immunodiffusion for antibody detection and an indirect immunofluorescent antibody test; however, these tests need further evaluation to be used in clinical practice.<sup>22,23</sup>

Rapid antigen detection assays with high sensitivity and specificity have been developed.<sup>24,25</sup> Sensitive polymerase chain reaction–based assays of clinical samples for the rapid diagnosis of penicilliosis marneffei have also been described.<sup>26</sup>

## TREATMENT AND PROGNOSIS

If untreated, penicilliosis marneffei is fatal. Amphotericin B, with or without 5-flucytosine, has been successful in treating penicilliosis marneffei infection. In vitro testing shows only moderate activity of amphotericin against *P. marneffei*.<sup>27</sup> Azoles, particularly itraconazole and ketoconazole, are very active against *P. marneffei*, both clinically and in vitro. Fluconazole is the least active in vitro of the currently available azoles, and it has been associated with more failures than the other azoles. The echinocandin anidulofungin shows in vitro activity, but there is no reported clinical experience.<sup>28</sup> In one case series of penicilliosis marneffei in HIV-infected

patients, amphotericin B had a response rate of 77% compared with 75% and 30% with itraconazole and fluconazole, respectively.<sup>27</sup> In an open-label trial of the treatment of HIV-infected people with penicilliosis marneffei, amphotericin B was given at 0.6 mg/kg/day for 2 weeks, followed by itraconazole at 400 mg/day; 97.3% of patients responded.<sup>29</sup> Treatment options are determined by the clinical status of the patient and the availability and cost of the drugs. For severely ill patients, amphotericin B (0.5 to 0.7 mg/kg/day) is the drug of choice. For patients with less severe illness, itraconazole (400 mg/day) is indicated. Ketoconazole, given in a 400 mg/day dose, can be an effective and much less expensive alternative to itraconazole. The duration of treatment is determined by the immune status of the patient. For HIV patients, lifelong suppressive therapy with azoles may be needed because 30% of patients relapse after cessation of therapy. For immuno-competent patients, there are not enough data to support a specific duration of treatment; however, 2 or 3 months has typically been associated with clinical resolution.<sup>10</sup> Clinical improvement is expected within 2 weeks of the institution of appropriate therapy.

If penicilliosis marneffei is not properly treated, the prognosis is poor, with high mortality in both HIV- and non-HIV-infected patients. Most HIV-infected patients who present with penicilliosis marneffei have a CD4 cell count of less than 50/ $\mu$ L as well as a history of other opportunistic infections.

## PREVENTION AND CONTROL

There is no evidence of human-to-human transmission. Itraconazole (200 mg/day) has been shown to prevent penicilliosis marneffei in AIDS patients in a highly endemic area of Thailand. However, overall survival was not improved.<sup>30</sup> Several vaccine technologies based on the secreted cell wall antigen Mp1p (DNA by intramuscular administration, DNA vaccine delivered orally via live attenuated *Salmonella typhimurium*, and recombinant protein administered by intraperitoneal injection) were shown to be protective in a murine model of penicilliosis marneffei.<sup>31</sup>

# Mucocutaneous and Deeply Invasive Candidiasis

SHMUEL SHOHAM  
THOMAS J. WALSH

## INTRODUCTION AND EPIDEMIOLOGY

Candidal infections are an important cause of illness worldwide. *Candida* spp., particularly *Candida albicans*, are frequent human commensals, but a diverse range of infections can occur when host defenses break down or are breached. Mucocutaneous infections are common in all climates. In hot, humid, tropical regions, macerated skin often becomes infected, resulting in cutaneous candidiasis. Mucosal candidiasis can involve the lower genital tract, oropharynx, or esophagus. Vulvovaginal candidiasis is one of the most common genital problems of women in both industrialized and developing countries. Extensive use of antibiotics, development of human immunodeficiency virus (HIV) infection, the advent of diabetes mellitus as a global health problem, and local genital immune factors are all contributors to the widespread prevalence of vulvovaginal candidiasis. Oropharyngeal and esophageal candidiasis are typically encountered in association with local mucosal injury or as a result of defects in cell-mediated immunity. In many countries, the major driving force for these illnesses is the HIV pandemic. Moreover, with the advent of globalization, illnesses previously associated with wealthier societies can be expected to assume an increasingly important role in developing nations. In that regard, in newly industrialized countries, deeply invasive candidiasis occurring in the setting of or, as a consequence of, medical progress will likely emerge as a new challenge. Examples of such illnesses include oropharyngeal and esophageal candidiasis among recipients of cytotoxic therapies, bloodstream infection in persons with indwelling vascular devices, and disseminated candidiasis in highly compromised hosts such as neonates and transplant recipients. Expansion of populations at risk, changes in distribution of colonizing and infecting species, and the impact of widespread use of antifungal agents on the evolution of resistant organisms are now experienced in an increasing number of regions worldwide. Studies designed to optimize use of existing antifungals and to aid in the development of novel agents continue to be crucial in meeting these challenges. Perhaps even more important is expansion of our knowledge of regional and global epidemiologic patterns,

candidal pathogenesis and host defenses, and the translation of this information into a better understanding of the fungus as it relates to patients in a diversity of environments.

## AGENTS

The genus *Candida* encompasses more than 150 species, but only a small number are human pathogens. In nature, *Candida* spp. are principally associated with plants and rotting vegetation. Most are unable to grow at temperatures of 37°C and require vitamins produced mainly in plant materials.<sup>1,2</sup> Of the species known to cause human disease, *Candida albicans*, *Candida glabrata*, *Candida parapsilosis*, *Candida tropicalis*, *Candida krusei*, *Candida lusitanae*, and *Candida guilliermondii* are the most commonly encountered pathogens.<sup>3-6</sup> Other species implicated in human disease include *Candida catenulata*, *Candida famata*, *Candida haemulonii*, *Candida inconspicua*, *Candida kefyr*, *Candida lambica*, *Candida lipolytica*, *Candida norvegensis*, *Candida pelliculosa*, *Candida pulcherrima*, *Candida rugosa*, *Candida sake*, *Candida utilis*, *Candida wiswanathii*, and *Candida zeylanoides*. Recently, *Candida dubliniensis* has been identified as a novel species that is increasingly being reported as a human pathogen.<sup>7,8</sup> Because *C. dubliniensis* shares many characteristics with *C. albicans*, it may be misidentified as *C. albicans* in clinical specimens.<sup>9</sup>

Laboratory identification of *Candida* spp. is achieved by assessment of a combination of morphologic and biochemical features of the fungus. *Candida* spp. grow as ovoid-shaped yeasts (blastoconidia), typically 4 to 6 µm in diameter, that reproduce by budding. Most species of *Candida* also produce filamentous growth in the form of pseudohyphae. *C. albicans* and *C. dubliniensis* are capable of producing both pseudohyphae and true hyphae.<sup>2</sup> Microscopic examination of yeast, hyphae, and pseudohyphae from clinical specimens is facilitated by the addition of 10% potassium hydroxide (KOH), which digests epithelial cells. Fluorescent microscopy of specimens stained with calcofluor white and the Gram method (*Candida* spp. stain gram-positive) are also useful diagnostic tools.

Phase transition from yeast to filamentous forms may be an important virulence factor in vivo. Germination can be induced under various conditions including the presence of serum, specific carbon sources, hemin, temperatures over 35°C, and pH of 6.5 to 7.0 or slightly alkaline. Conversely, lower temperatures and an acid environment favor yeast growth.<sup>2,10</sup> During hyphal formation, an outgrowth develops from the yeast cells termed a germ tube. Diagnostic mycology laboratories commonly test for the presence or absence of a germ tube in order to differentiate *C. albicans* and *C. dubliniensis* from other *Candida* spp. Development of a germ tube is highly suggestive but not absolutely diagnostic for these two species. Additionally, *C. albicans* and *C. dubliniensis* can produce large (8 to 12 µm), thick-walled cells termed chlamydospores. Chlamydospores are occasionally encountered in host tissue and can be induced by various culture media including corn meal agar, rice extract agar, chlamydospore agar, PCB, Tween 80-oxgall-cafeic acid, and diluted milk.<sup>2,11,12</sup>

Clinically important species of *Candida* grow well in routine blood culture systems and on common mycologic and bacteriologic media including Sabouraud glucose agar, sheep

blood agar, and horse blood agar.<sup>13</sup> When grown at 25°C to 37°C on Sabouraud agar, *Candida* spp. form white-to-beige colonies that are smooth-to-wrinkled in texture. Media containing chromogenic compounds such as CHROMagar can differentiate *Candida* spp. based on the formation of various colored colonies with different morphologies, which result from the cleavage of chromogenic substrates by species-specific enzymes. CHROMagar *Candida* medium (CCM) can be used for presumptive identification of *C. albicans*, *C. tropicalis*, and *C. krusei*.<sup>14</sup> In a study exploring the usefulness of CCM in a developing country, more than 90% of isolates from clinical specimens were identified to species level within 48 hours, and the assay was determined to be cost effective in a resource-poor environment.<sup>15</sup> CCM can be used to distinguish *C. albicans* from *C. dubliniensis*. Upon primary plating of the clinical specimen on CCM, *C. dubliniensis* produces dark-green colonies, whereas *C. albicans* appears light blue-green.<sup>13</sup> Definitive identification of *Candida* spp. can be facilitated by metabolic tests. Commercial kits are now available that provide standardized identification of most *Candida* spp. within several days. In addition to the use of CHROMagar as described previously, *C. albicans* can be differentiated from *C. dubliniensis* by the latter's inability to grow at 45°C and by use of species-specific DNA fingerprinting probes.<sup>16,17</sup>

## **PATHOGENESIS AND IMMUNITY**

*Candida* spp., particularly *C. albicans*, colonize the human gastrointestinal, respiratory, and reproductive tracts and the skin. Invasive disease occurs when host defenses break down or are breached. A variety of adhesins facilitate attachment of the fungus to epithelial and endothelial surfaces.<sup>18</sup> The ability of *Candida* spp. to form biofilms on surfaces such as catheters has contributed to the emergence of these fungi as major pathogens of patients with indwelling medical devices. Biofilm-associated infections are frequently refractory to antifungal therapy. This resistance could be due in part to changes in candidal sterol composition and upregulation of drug efflux pumps.<sup>19,20</sup> Production of hydrolytic enzymes including secreted aspartic proteinases, phospholipases, and lipases have all been linked to virulence of *C. albicans*.<sup>21</sup> Secreted aspartyl proteinases digest molecules for nutrient acquisition, disrupt host cell membranes to facilitate adhesion and tissue invasion, and break up cells and molecules of the immune system, thereby contributing to the infectious process.<sup>22</sup> Phospholipases promote fungal virulence through host cell damage and lysis.<sup>23</sup> Morphologic transitions among yeast, pseudohyphal, and hyphal forms and the phenomenon of phenotype switching are also thought to contribute to virulence in *C. albicans*.<sup>24,25</sup> Other virulence factors include production of a hemolytic factor that facilitates acquisition of iron by the pathogen and expression of complement receptors that act to inhibit phagocytosis.<sup>26,27</sup>

Clinical disease can be broadly divided into two categories: mucosal and systemic candidiasis. Innate immunity is the dominant protective mechanism against disseminated disease. Neutrophils, monocytes, endothelial cells, dendritic cells, platelets, opsonins, cytokines, chemokines, and complement all participate in protection against systemic infection.<sup>28,29</sup> The role of cell-mediated immunity and antibodies in disseminated

disease is less clear. Cell-mediated immunity is the predominant protective mechanism against nongenital mucosal candidiasis. Clinically, patients with abnormal cell-mediated immune responses as a consequence of HIV infection or corticosteroid use are at increased risk for mucosal infections. In the lower genital tract, locally acquired mucosal immunity appears to be more important than systemic cell-mediated immunity against *C. albicans* infection, and the majority of women with candidal vaginitis do not have a discernible systemic immune defect.<sup>30,31</sup>

## **ANTIFUNGAL SUSCEPTIBILITY**

Antifungal agents belonging to four major classes—azoles, polyenes, echinocandins, and pyrimidine analogs—are used to treat most candidal infections. This section describes the mechanisms of action of drugs belonging to these classes, means by which *Candida* spp. have developed resistance, and epidemiologic patterns of antifungal susceptibility.

The antifungal compounds belonging to the azole class target ergosterol biosynthesis by inhibiting the fungal cytochrome P-450-dependent enzyme lanosterol 14 $\alpha$ -demethylase. This inhibition interrupts the conversion of lanosterol to ergosterol, which leads to accumulation of aberrant 14 $\alpha$ -methylsterols and depletion of ergosterol in the fungal cell membrane. This interruption alters the fungal cell membrane properties and functions and, depending on organism and compound, may lead to fungal cell death or inhibition of cell growth and replication. In addition, the azoles also inhibit cytochrome P-450-dependent enzymes of the fungal respiration chain.<sup>32</sup> Resistance to azoles may be intrinsic, as in the case of some isolates of *C. krusei*, or acquired. Several mechanisms of azole resistance have been described in *Candida* spp. Factors contributing to decreased azole susceptibility include reduced affinity of 14 $\alpha$ -demethylase to fluconazole, enhanced 14 $\alpha$ -demethylation (related increased expression of *erg 11*, which allows the organism to overcome enzymatic inhibition, alteration of the ergosterol biosynthetic pathway, and upregulation of multidrug efflux transporters.<sup>33–36</sup> These mechanisms frequently operate simultaneously to exert antifungal resistance. Genetic analyses in *C. albicans* have demonstrated that under antifungal pressure clinical isolates can undergo minor genetic alterations that over time lead to gradual development of azole resistance through the accumulation of different molecular mechanisms.<sup>37</sup>

*C. albicans* is the most common *Candida* sp. recovered from mucocutaneous candidiasis. Most isolates are susceptible to all antifungal agents; however, emergence of resistance to azoles may be common in isolates of *C. albicans*. The most common *Candida* spp. encountered in clinical settings of bloodstream infection are *C. albicans*, *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, and *C. krusei*. Although *C. albicans*, *C. tropicalis*, and *C. parapsilosis*, which account for more than two thirds of bloodstream infections, remain susceptible to fluconazole and itraconazole, resistance among *C. glabrata* and *C. krusei* has emerged as an issue with clinically relevant implications.<sup>38</sup> A breakpoint for fluconazole susceptibility has been set when the minimum inhibitory concentrations (MICs) are less than or equal to 8  $\mu$ g/mL. Isolates for which the MIC of fluconazole is between 16 to 32  $\mu$ g/mL are considered susceptible dependent upon dose (S-DD) and resistant when

the MIC is greater than or equal to 64 µg/mL.<sup>39</sup> S-DD isolates may be treated successfully with higher dosages of fluconazole.

In a 10-year study assessing the antifungal susceptibilities of *Candida* spp. collected from 250 medical centers in 32 nations, more than 90% of *C. albicans*, *C. tropicalis*, and *C. parapsilosis* were found to be susceptible to fluconazole.<sup>5</sup> In a recent survey, 1.2% of *C. albicans* isolates were resistant to fluconazole compared with 6% of *C. tropicalis* isolates.<sup>38</sup> *C. glabrata* has emerged as a major cause of invasive candidiasis. In a study involving more than 200 medical centers worldwide, 60% of *C. glabrata* isolates were susceptible to fluconazole, 32% were S-DD, and 8% were resistant.<sup>40</sup> In that study, only 5% of *C. krusei* isolates were susceptible to fluconazole, 50% were S-DD, and 45% were resistant. Whereas *C. albicans*, *C. tropicalis*, and *C. parapsilosis* have generally remained sensitive to itraconazole, in an international study more than one third of *C. glabrata* and *C. krusei* isolates were found to have decreased susceptibility to that agent.<sup>41</sup> In vitro, nearly all isolates of *C. krusei* are susceptible to voriconazole (MIC <1 µg/mL), irrespective of their level of resistance to fluconazole.<sup>40</sup> However, fluconazole-resistant isolates of *C. albicans* and *C. glabrata* can have substantial in vitro cross-resistance to voriconazole.

Amphotericin B primarily acts by binding to ergosterol, the principal sterol in the cell membrane of most fungi, leading to the formation of ion channels and concentration-dependent cell death. These pores, composed of amphotericin B multimers, form most readily when ergosterol is present in the cell membrane.<sup>42,43</sup> Resistance to polyenes (amphotericin B and nystatin) has been reported in *Candida* spp. including *C. lusitanae*, *C. tropicalis*, *C. glabrata*, and *C. albicans*.<sup>35,44,45</sup> Mechanisms of resistance include loss or marked depression of ergosterol in the cell membrane and increased catalase activity with resultant protection against polyene-induced oxidative damage.<sup>45,46</sup> Clinical isolates of *C. albicans* with mutations in the  $\delta$ -5,6-sterol desaturase gene with associated alteration in the ergosterol biosynthetic pathway have been described. These fluconazole-resistant isolates lack ergosterol in the cytoplasmic membrane and thereby also demonstrate reduced susceptibility to amphotericin B.<sup>47</sup> In epidemiologic studies, the majority of *Candida* spp. remain sensitive to amphotericin B, but reduced susceptibility has been noted as described previously.<sup>40,48</sup>

The echinocandins are a novel class of semisynthetic amphophilic lipopeptides composed of a cyclic hexapeptide core linked to a variably configured lipid side chain. The echinocandins act by noncompetitive inhibition of the synthesis of 1,3- $\beta$ -glucan, a polysaccharide in the cell wall of many pathogenic fungi. Together with chitin, the ropelike glucan fibrils are responsible for the cell wall's strength and shape, are important in maintaining the osmotic integrity of the fungal cell, and play a key role in cell division and cell growth.<sup>49,50</sup> Echinocandin-resistant mutants of *C. albicans* have been created under laboratory conditions.<sup>51</sup> Although there are currently no established interpretive breakpoints for susceptibility, in a recent study caspofungin showed excellent in vitro activity against *Candida* spp.<sup>48</sup> The MICs of caspofungin for *C. parapsilosis* tend to be higher, but the clinical significance of this observation is unknown at this time.

Flucytosine (5-fluorocytosine; 5-FC) is a low-molecular-weight, water-soluble, synthetic, fluorinated analog of cytosine.

5-FC has no antifungal activity of its own. It is taken up by the fungus-specific enzyme cytosine permease and converted in the cytoplasm by cytosine deaminase to 5-fluorouracil, which causes RNA miscoding and inhibits DNA synthesis.<sup>52</sup> Resistance to 5-FC may occur as a result of decreased cellular uptake as occurs in *C. glabrata* isolates with a defect in cytosine permease.<sup>53</sup> Resistance may also occur as a result of failure to metabolize 5-FC to intracellularly active metabolites such as 5-fluorouridylic acid (FUMP).<sup>36</sup> Primary resistance to 5-FC is uncommon among most clinically relevant *Candida* spp. In a study of more than 8800 clinical isolates from over 200 centers worldwide, 95% were sensitive (MIC  $\leq$ 4 µg/mL), 2% intermediate (MIC 8 to 16 µg/mL), and 3% resistant (MIC  $\geq$ 32 µg/mL). In that same study, however, primary resistance was frequently observed among isolates of *C. krusei* (5% S, 67% I, and 28% R).<sup>54</sup> Acquired resistance to 5-FC is far more prevalent. Because such resistance can occur during monotherapy, 5-FC generally is used in combination with other antifungal agents.

## ■ Infections of Skin and Nails

### CLINICAL MANIFESTATIONS

*Candida* spp., particularly *C. albicans* and *C. parapsilosis*, are frequent colonizers of skin. The skin of up to one third of healthy adults may be colonized with *C. parapsilosis*.<sup>55</sup> Factors associated with colonization include antibiotic therapy, parenteral nutrition, low birth body mass in infants, endotracheal intubation, duration of stay for hospitalized patients, indwelling intravenous catheters, malignancies, diabetes mellitus, surgery, aging, and obesity.<sup>56,57</sup> Superficial infections due to *Candida* spp. regularly involve intertriginous or occluded areas, glabrous skin, and the nails.<sup>58</sup> *Candida* spp. frequently cause infections at large skin folds. Warm, moist surfaces and macerated skin favor superficial candidal infection. Affected sites include the groin and perianal regions, skin under pendulous breasts or large abdominal folds, and the axilla. Environmental conditions such as hot, humid weather, crowding, and poor personal hygiene predispose to candidal intertrigo.<sup>59</sup> Diabetes mellitus is a major risk factor for superficial candidiasis and has emerged as a problem in some tropical regions.<sup>60</sup> Additional host factors such as obesity, receipt of antibiotics or steroids, inflammatory skin diseases, and infections with HIV and human T-lymphotropic virus type 1 (HTLV-1) also predispose to cutaneous candidiasis.<sup>61–63</sup>

These cutaneous lesions consist of pruritic and sometimes painful, moist, erythematous plaques or macules. The involved skin may be eroded, and whitish scaling is often seen at the borders of lesions. Erythematous vesiculopapular or pustular satellite lesions are common. The latter may coalesce to extend the infection. *C. albicans* originating from the gastrointestinal tract plays a major role in diaper dermatitis.<sup>64,65</sup> Candidal diaper dermatitis is more common when non-disposable diapers are used. The warm, moist, occlusive environment beneath the diaper facilitates infection. The rash, which typically presents as a sharply marginated area of erythema, starts at the perianal region but may extend to involve the anterior thighs, genital creases, abdomen, and genitalia.<sup>66</sup> *Candida* miliaria, which starts out with vesiculopustular

lesions, affects the backs of bedridden patients, particularly those who are sweating profusely.<sup>67</sup> *Candida* spp. have been reported to cause painful cutaneous and perhaps ductal infection of the mammary gland in lactating women and may be a cause of premature weaning among lactating mothers.<sup>68</sup> Angular cheilitis presents with macerated skin, pain, erythema, and fissures at the angles of the mouth. It can be unilateral or bilateral and often is caused by *C. albicans*.<sup>69</sup> *Candida* spp. may infect hair follicles. Predisposing factors for candidal folliculitis include use of steroids and antibiotics; however, these need not be present.<sup>70,71</sup> Infection may involve the beard area (folliculitis barbae candidomycetica) and present as erythematous plaques, papules, or pustules.

Candidal interdigital infections (erosio interdigitalis blastomycetica) and paronychia are common in the tropics. These conditions occur most commonly following prolonged immersion of hands in water or wearing of occlusive gloves. Dishwashers, laundry workers, and gardeners are at risk.<sup>72</sup> The clinical appearance of interdigital infection consists of a painful, erythematous, eroded area between the fingers or toes. Paronychia presents with redness, swelling, and tenderness at the nail fold that may extend beneath the nail. The infection can progress to involve the nail itself. However, candidal onychomycosis may occur without antecedent paronychia. *Candida* spp. play a relatively minor role in toenail onychomycosis but are frequently found in fingernail infections.<sup>73,74</sup> *C. albicans* and *C. parapsilosis* are the predominant species of *Candida* causing onychomycosis.<sup>75,76</sup>

Cutaneous candidal infections generally respond well to topical nystatin or imidazole derivatives.<sup>77,78</sup> Measures that promote dryness are important, and in that regard nystatin and miconazole in a powder vehicle are useful options. Topical corticosteroids are commonly added to the regimen and can provide rapid relief of symptoms.<sup>79,80</sup> In cases of extensive skin involvement, systemic therapy may be required. Infections of the nail fold can usually be managed with modification of the predisposing occupational factors, drainage, and topical antifungals. In recalcitrant cases or when the nail itself is involved, systemic therapy should be employed.<sup>81</sup> Candidal onychomycosis responds well to oral itraconazole.<sup>82</sup>

## CONGENITAL CUTANEOUS CANDIDIASIS

Congenital cutaneous candidiasis presents at birth or soon thereafter. The syndrome is likely secondary to contamination of skin from a maternal source. Typically there is a generalized eruption of erythematous macules, papules, or pustules that sometimes evolve to vesicles and bullae. Involvement of the palms and soles is frequent. Very low-birth-weight infants may develop desquamating or erosive dermatitis. There often is evidence of an intrauterine infection with *Candida*.<sup>83</sup> Topical therapy with either nystatin or imidazole derivatives is generally sufficient.<sup>84,85</sup> Some infants may present with respiratory distress or clinical signs of sepsis during the first 2 days of life.<sup>86</sup> Such patients should be treated with systemic antifungals. Systemically disseminated candidiasis is far more common in neonates weighing less than 1000 g. Consequently, low-birth-weight neonates or infants with prolonged rupture of membranes who demonstrate clinical findings of disseminated neonatal cutaneous candidiasis should be

treated with systemic antifungals.<sup>87,88</sup> Invasive fungal dermatitis is a newly described clinical entity characterized by erosive, crusting lesions that develop 1 to 2 weeks after birth in extremely low-birth-weight neonates. *C. albicans* is the most commonly implicated pathogen, and dissemination is common.<sup>89</sup>

## CHRONIC MUCOCUTANEOUS CANDIDIASIS

Chronic mucocutaneous candidiasis (CMC) is a group of disorders that typically present during childhood and is characterized by recurrent and persistent candidal infections, which may involve the skin, nails, and mucosal surfaces. Patients with CMC have impaired cell-mediated responses to *Candida* spp. and subsequently are unable to effectively clear these organisms. In patients with CMC, candidal antigens trigger a predominantly Th2 instead of a Th1 cytokine response.<sup>90–92</sup> Additional immune defects that have been described in patients with CMC are subtle alterations in antibody responses to bacteria and fungi and impaired granulocyte and natural killer cell function.<sup>93–95</sup> Severity and distribution of candidal infections vary. In some patients, infections are limited to the nails, whereas in others the candidiasis is extensive and disfiguring. The initial presentation is typically oral candidiasis or diaper dermatitis. Angular cheilitis, lip fissures, paronychia, and onychia are common manifestations. Cutaneous findings include erythematous skin lesions with serpiginous borders. Local or diffuse dermatophytosis may coexist with cutaneous candidiasis.<sup>96</sup> *Candida* granuloma in CMC is characterized by highly disfiguring hyperkeratotic, well-demarcated lesions of the face, eyelids, scalp, lips, or acral areas that may grow to several centimeters and take a hornlike appearance.<sup>67</sup> Mucosal manifestations of CMC include vulvovaginitis and infections of the oropharynx, larynx, and esophagus. Oral, laryngeal, and esophageal candidiasis may occur together or independently. Symptoms include hoarseness, dysphagia, and rarely hemoptysis. The signs and symptoms of laryngitis or esophagitis can be minimal or absent, but esophageal strictures can arise from chronic inflammation.<sup>97</sup> CMC occurs in isolation and in association with a variety of endocrine, autoimmune, and infectious disorders. These include endocrinopathies such as hypoparathyroidism, thyroid abnormalities and Addison's disease, dental enamel dysplasia, interstitial keratitis, vitiligo, and alopecia totalis.<sup>98</sup> Deeply invasive candidiasis is rare in CMC. Recurrent and severe noncandidal infections are common and include septicemia, bacterial pneumonia, bronchiectasis, and opportunistic infections, including cryptococcal meningitis and disseminated histoplasmosis.<sup>99–101</sup> An adult form of CMC that typically presents after the third decade of life is associated with thymoma, myasthenia gravis, hypogammaglobulinemia, and abnormalities of the bone marrow and circulating blood elements.<sup>102</sup> CMC can occur sporadically or as a familial disease with either autosomal dominant or recessive patterns of inheritance. Treatment requires systemic antifungal therapy. The advent of azole antifungals has revolutionized the care of these patients. Clinical responses may be slow, and infections often require months of treatment to clear. Long-term therapy should be individualized, and most patients require intermittent treatment or chronic suppression to remain in remission. Relapses while

on treatment and acquisition of resistance to azole antifungals can occur.<sup>103–108</sup> Patients with early manifestations of CMC should be evaluated for HIV infection.

## CUTANEOUS PRESENTATION OF DISSEMINATED CANDIDIASIS

Hematogenously disseminated candidiasis can present with cutaneous manifestations.<sup>109–112</sup> The characteristic lesions consist of single or multiple 0.5- to 1-cm erythematous or purpuric papulonodules with pale centers. In highly compromised hosts, these lesions may be the initial manifestation of candidemia. A syndrome of disseminated candidiasis with extensive folliculitis has been described in injection heroin abusers.<sup>113,114</sup> Less commonly, disseminated infection presents as ecthyma gangrenosum or purpura fulminans.<sup>115–117</sup> Histologic evaluation of specimens obtained by skin biopsy are extremely useful and often establish the diagnosis of disseminated candidiasis prior to growth of the organism in blood cultures.<sup>118</sup> Management of systemic infection is described elsewhere in this chapter.

## ■ Oropharyngeal Candidiasis

### EPIDEMIOLOGY AND PATHOGENESIS

Oropharyngeal candidiasis (OPC) is the most common mycotic infection of the oral cavity. *Candida* spp. frequently colonize the oral cavity. Multiple factors affect colonization, including HIV status and levels of serum HIV RNA, increasing age, use of dentures, receipt of antibiotics, malnutrition, and oral hygiene.<sup>119–127</sup> The most common colonizing species is *C. albicans*, although non-*albicans* species of *Candida* are increasingly identified. The development of infection depends upon both systemic and local determinants. Extremes in age, diabetes mellitus (particularly when glycemic control is poor), nutritional deficiencies, and immunosuppression (especially of cell-mediated immunity) are all systemic risk factors for oral candidiasis. Local factors that promote infection include the presence of dentures (especially when fit is inadequate), salivary abnormalities such as Sjögren's disease, treatment with inhaled steroids, and destruction of natural mucosal barriers with radiotherapy for head and neck cancers or cytotoxic chemotherapy.<sup>128–135</sup> HIV infection, which has become endemic in many regions, is one of the most important predisposing conditions worldwide. Oropharyngeal colonization with *Candida* spp. is more prevalent among seropositive persons and correlates with serum HIV-1 RNA levels.<sup>125,136</sup> In HIV-infected individuals, OPC is a leading cause of oral disease and is significantly associated with lower median CD4 lymphocyte counts, especially below 200/ $\mu$ L.<sup>137–139</sup> Unless antiretroviral therapy is initiated, the presence of oral candidiasis predicts the development of other serious opportunistic infections of AIDS.<sup>140,141</sup> Therapy with highly active antiretroviral therapy (HAART) is associated with significant decreases in the prevalence of OPC. This effect may be due to a combination of factors including immune reconstitution, decreased viral load, and antagonism of candidal virulence factors by protease inhibitors.<sup>142–144</sup>

## AGENTS

The etiologic agent in OPC is almost always *C. albicans*; however, non-*albicans* species of *Candida* have emerged as both colonizing and infecting species in recipients of radiotherapy for head and neck malignancies, in patients with HIV, and in those with extensive past antifungal exposure.<sup>145–149</sup> *C. dubliniensis*, which has recently been differentiated from *C. albicans*, is increasingly recognized in OPC. This organism may be misidentified as *C. albicans*, and some isolates of *C. dubliniensis* have decreased susceptibility to azole antifungals.<sup>150–152</sup> *C. albicans* with reduced susceptibility to fluconazole can colonize or infect severely immunosuppressed individuals, especially when there has been extensive exposure to azoles, and such isolates may be transmitted by person-to-person spread.<sup>149,153,154</sup> In mucosal candidiasis refractory to clotrimazole, strains of *C. albicans* with cross-resistance to other azoles have been observed.<sup>155</sup>

## CLINICAL MANIFESTATIONS

The clinical manifestations of OPC are diverse, and multiple forms frequently present concurrently. Pseudomembranous candidiasis, or thrush, is the most commonly encountered type. The condition is characterized by curdlike, white patches on the buccal mucosa, gingiva, palate, and tongue. The pseudomembranes may be scraped off to leave a raw, erythematous undersurface. The patches consist of desquamated epithelium, inflammatory cells, bacteria, fungal elements, keratin, and food debris. The diagnosis is suggested by the characteristic appearance of the lesions. Microscopically, yeast forms, hyphae, and pseudohyphae are evident on KOH smear or Gram stain. Erythematous candidiasis (acute atrophic candidiasis) occurs by itself or in association with the pseudomembranes.<sup>141,156</sup> In some cases, erythematous candidiasis occurs as a result of sloughing of the pseudomembranes. The flat, red, occasionally painful lesions are typically present on the dorsal surface of the tongue. The erythematous form of candidiasis is more difficult to recognize and is likely underdiagnosed. Median rhomboid glossitis, which presents as a smooth, sometimes raised, erythematous lesion at the midline of the dorsal surface of the tongue, was previously thought to be a developmental abnormality, but is now recognized as a manifestation of infection by *Candida*. Chronic atrophic candidiasis, which presents with mucosal erythema and edema, affects areas of persistent local trauma due to denture wear. A related condition, *Candida*-associated palatal papillary hyperplasia has been described in HIV-infected patients.<sup>157</sup> Angular cheilitis, inflammation at the angles of the mouth, can be precipitated by a number of causes including candidal infection. The lesions of chronic hyperplastic candidiasis (candidal leukoplakia) typically present as adherent, firm, elevated white patches on the buccal mucosa or tongue. This condition can be resistant to treatment and on rare occasions may develop into carcinoma.<sup>158</sup> *C. albicans* is associated with black hairy tongue, which is characterized by hypertrophy of the filiform papillae on the surface of the tongue. Black hairy tongue typically occurs following antibiotic use. Patients may complain of a tickling sensation, and treatment consists of physical débridement and good oral hygiene.<sup>67</sup>

## TREATMENT

The major therapeutic options available for treating oral candidiasis are topical azoles (clotrimazole troches), oral azoles (fluconazole, ketoconazole, or itraconazole), oral polyenes (nystatin or amphotericin B), intravenous amphotericin B, and intravenous echinocandins (caspofungin).<sup>88</sup> Most patients respond to either topical or oral systemic therapy as initial treatment of OPC. Topical therapy with five times daily clotrimazole troches (10 mg) or four times daily nystatin (500,000 units in suspension or pastille form) is generally effective. However, systemic therapy may be advantageous in certain circumstances. In a comparative study of patients with HIV-associated OPC, the clinical efficacy of 14 days of fluconazole (100 mg daily) was equivalent to clotrimazole (10 mg five times daily) (98% vs. 94%;  $P = \text{NS}$ ).<sup>159</sup> In that patient population, however, fluconazole has been associated with higher rates of mycologic eradication and fewer relapses.<sup>139,159</sup> In another study of patients with HIV-associated OPC, the clinical efficacy of liquid suspension fluconazole (100 mg once daily for 14 days) was superior to that of liquid nystatin (500,000 units four times daily for 14 days) (87% vs. 52%).<sup>160</sup> Additionally, there were fewer relapses among those patients receiving fluconazole.

Fluconazole appears to be more efficacious than ketoconazole in OPC. The rate of clinical cure of HIV-associated OPC with fluconazole (50 mg daily) was 100% compared with 75% for ketoconazole (200 mg daily).<sup>161</sup> In a study of children with HIV-associated OPC, oral fluconazole (3 mg/kg/d) and ketoconazole (7 mg/kg/d) had comparable safety and relapse rates. In that study, patients treated with fluconazole had higher clinical and mycologic cure rates at the end of therapy (88% and 71%, respectively) than those treated with ketoconazole (81% and 57%, respectively).<sup>162</sup> Itraconazole cyclodextrin solution achieves higher serum itraconazole concentrations than the capsule formulation and, if available, is the preferred form.<sup>163</sup> Itraconazole oral solution at 100 and 200 mg daily is well tolerated and as effective as fluconazole 100 mg tablets.<sup>164,165</sup> In a study of children over 5 years of age and adolescents with HIV-associated OPC, itraconazole cyclodextrin oral solution (2.5 mg/kg twice daily) was well tolerated and efficacious.<sup>166</sup> In that study, all patients with fluconazole-resistant isolates responded to treatment with the itraconazole solution. Furthermore, there was no clear correlation between in vitro susceptibilities to itraconazole and response to therapy.

In the 1990s, fluconazole-refractory OPC emerged as problem in HIV-infected patients.<sup>167–170</sup> In a cohort of persons with advanced HIV, this condition was identified in approximately 4% of patients and was associated with a poor overall prognosis (median survival after diagnosis, 32.6 weeks).<sup>171</sup> In most cases the infecting organism was *C. albicans*, and isolation of non-*albicans* *Candida* spp. remains uncommon. Profound immunosuppression and exposure to fluconazole have been recognized as risk factors, and many of the isolates have reduced in vitro susceptibility to fluconazole.<sup>172–174</sup> Various therapeutic options are available. Fluconazole may be given in “swish and swallow” formulation as topical therapy in cases refractory to the tablet form.<sup>175</sup> For OPC due to fluconazole-resistant or dose-dependent susceptible strains of *Candida*, increasing the dose of fluconazole up to a maximum of 800 mg daily and treating with longer courses of therapy

are often successful.<sup>176</sup> As indicated previously, itraconazole oral solution (100 to 200 mg twice daily in adults and 2.5 mg/kg twice daily in children) can be effective in fluconazole-unresponsive OPC.<sup>166,177</sup> Additional options for recalcitrant infections include oral amphotericin B, intravenous caspofungin, combination therapy with fluconazole and terbinafine (250 mg/d) or sargramostim (GM-CSF 2.5  $\mu\text{g/kg/d}$ ).<sup>178–182</sup> Amphotericin B oral suspension, although well tolerated, has limited efficacy for the treatment of fluconazole-refractory oral candidiasis.<sup>174</sup>

Prophylactic antifungal therapy may be employed in patients at high risk for infection and in cases of recurrent disease. Oral clotrimazole is effective as prophylaxis in cancer patients and solid organ transplant recipients.<sup>183–185</sup> Fluconazole at 100 or 200 mg daily significantly reduces colonization and infection in high-risk patients, but resistance can develop on therapy.<sup>186–188</sup>

Some regions in developing countries with limited resources may not have access to standard antifungal therapy for treatment of oropharyngeal candidiasis. In such settings, gentian violet may be as effective as nystatin or ketoconazole.<sup>189</sup> A randomized, open label study of the treatment of oropharyngeal and esophageal candidiasis was conducted in Kinshasa (Zaire) among 141 inpatients with AIDS and oropharyngeal candidiasis, 136 of whom also had esophageal candidiasis. The study compared the efficacy of gentian violet mouth washes (1.5 mL 0.5% aqueous solution twice daily), oral ketoconazole (200 mg/d, after a meal), and nystatin mouth washes (200,000 units oral suspension four times daily). Patients enrolled in this study had a very high mortality (probability of death, 41.6% after 14 days). After 14 days, 72 patients could be evaluated. At that time, oropharyngeal lesions had disappeared in similar proportions of patients treated with gentian violet (11/26, 42%) and ketoconazole (10/23, 43%) and in a lower proportion of patients treated with nystatin (2/23, 9%;  $P < 0.05$ ). In esophageal candidiasis, ketoconazole seemed more efficient than both other treatments. This study suggests that gentian violet is an effective and relatively inexpensive (0.5 US\$/treatment course in Kinshasa) alternative for treatment of oropharyngeal candidiasis.

## ■ Esophageal Candidiasis

### CLINICAL MANIFESTATIONS

*Candida* is a frequent colonizer of the esophagus. *C. albicans* is the major colonizing and infecting species.<sup>190,191</sup> Factors associated with esophageal candidiasis include HIV infection, organ transplantation, alcoholic liver disease, receipt of antibiotics, treatment with proton pump inhibitors, and defects in cell-mediated immunity.<sup>192–196</sup> Local factors such as receipt of inhaled steroids and esophageal carcinoma also predispose to esophageal candidiasis.<sup>197–198</sup> In HIV-infected patients with upper digestive symptoms, esophageal candidiasis is the most common cause, although sometimes multiple concurrent opportunistic infections including CMV and HSV exist. In this population, development of esophageal candidiasis is associated with low CD4 counts, high serum HIV RNA levels, antibiotic use, and concurrent or previous oropharyngeal candidiasis.<sup>199,200</sup>

Symptoms typically include odynophagia, dysphagia, and retrosternal pain, although esophageal candidiasis can be asymptomatic and discovered only on endoscopy. Infection is generally limited to the mucosa, but in highly compromised hosts transmural necrosis leading to perforation and invasion into deeper mediastinal structures may occur.<sup>201</sup> Esophageal strictures leading to stenosis can also complicate the course of patients with esophageal candidiasis.<sup>202</sup>

## DIAGNOSIS

Radiologic studies can assist in the evaluation of patients. Typical early-stage findings include edematous esophageal folds with subsequent development of plaques and diffuse ulceration.<sup>203</sup> Less common radiologic manifestations are discrete ulcers, which may be mistaken for viral esophagitis, or innumerable, tiny (1- to 3-mm), round lucencies that take on the appearance of a layer of foam (foamy esophagus).<sup>204,205</sup>

Although it is more invasive, endoscopy offers the advantage of direct examination of the esophagus for the characteristic findings of candidal esophagitis. Furthermore, cytologic brushing or biopsy can be performed for the purpose of microbiological and histopathologic evaluation. The most common endoscopic findings are white mucosal plaques, which consist of desquamated epithelium and inflammatory cells with infiltration by fungal elements and superinfecting bacteria. With increasing severity, the scattered mucosal plaques coalesce to form circumferential disease and ultimately can cause luminal impingement.<sup>206</sup> The presence of white plaques in HIV-infected patients with dysphagia and odynophagia is highly predictive of esophageal candidiasis.<sup>207</sup>

## TREATMENT

A strategy whereby empirical fluconazole is given to HIV-infected patients with esophageal symptoms has been found to be safe and cost effective. However, clinical responses need to be monitored closely, and endoscopy should be pursued for establishment of diagnosis in patients who do not improve promptly.<sup>208–210</sup> This approach may be very attractive in resource-poor settings. Fluconazole is the mainstay of therapy for esophageal candidiasis, and response rates are typically greater than 80%.<sup>211,212</sup> Fluconazole (100 mg/d for 2 to 3 weeks) is highly effective in most cases. In comparative trials, fluconazole was superior to ketoconazole, flucytosine, and itraconazole capsules.<sup>213–215</sup> The efficacy of itraconazole capsules and flucytosine (100 mg/kg daily orally) in combination was found to be comparable to fluconazole.<sup>216</sup> Voriconazole (200 mg twice daily) is as effective as fluconazole and may have a role in fluconazole-resistant infections but is associated with more adverse reactions.<sup>217</sup>

Itraconazole oral solution has comparable efficacy with fluconazole, and at doses of 200 to 800 mg/d has been used successfully as salvage therapy in fluconazole-resistant cases.<sup>218,219</sup> For azole-refractory cases, intravenous amphotericin B is commonly used. Recently, antifungals of the echinocandin class have emerged as additional options.<sup>178,220</sup> In a trial of adults with candidal esophagitis, intravenous caspofungin at 50 or 70 mg daily was effective in 74% and 89% of cases, respectively.<sup>220</sup> In that same study, intravenous

amphotericin B (0.5 mg/kg daily) was effective in 63% of cases. In a trial comparing intravenous caspofungin (50 mg/d) and fluconazole (200 mg/d), the efficacy of the two agents was comparable (81% and 85%, respectively).<sup>212</sup> Esophageal candidiasis generally responds well to antifungal therapy. However, in persons with AIDS in the absence of immune reconstitution, recurrences are common, usually occurring within 2 to 3 months.<sup>221</sup> Prophylactic fluconazole (100 mg/d) is effective in preventing recurrences.<sup>222</sup>

## ■ Vulvovaginal Candidiasis

*Candida* spp. commonly colonize the lower genital tract of girls and women.<sup>223,224</sup> The rates of colonization decline with age.<sup>225</sup> The vast majority of isolated yeasts are *C. albicans*. Whereas most often these represent asymptomatic vaginal colonization, host factors such as receipt of antibiotics, diabetes mellitus, pregnancy, wearing of poorly ventilated clothing, and possibly the use of oral contraceptives can facilitate transformation to symptomatic vaginitis.<sup>226–228</sup> Most women will have at least one attack of vulvovaginal candidiasis in their lifetime. Vulvovaginal candidiasis is most common in women before menopause but rarely occurs before menarche. The relationship of HIV status to vulvovaginal candidiasis is far less established than for oropharyngeal infection. HIV seropositivity is associated with increased rates of vaginal colonization by *Candida*. However, the incidence of candidal vaginitis is not significantly elevated in HIV-seropositive women when compared with matched HIV-seronegative controls.<sup>138</sup> Clinical findings in vulvovaginal candidiasis consist of irritation, pruritus, erythema, edema, fissures, dysuria, and dyspareunia. The inflammation may extend throughout the vulva and into the perineum. A discharge, which can be thick, is often but not invariably present. Often the patient will make a self-diagnosis of “yeast” vaginitis. However, this may be unreliable and can lead to overuse of topical antifungal agents. In a patient with vaginitis, the presence of hyphae, pseudohyphae, and blastospores on microscopic evaluation of a sample treated with 10% KOH is highly suggestive of candidiasis. Estimation of the pH, the amine test, and saline microscopy are not sensitive or specific for vulvovaginal candidiasis but are useful in suggesting an alternative or concomitant cause for the symptoms. Vaginal cultures do not distinguish colonization from infection and are not commonly needed. Vaginal yeast cultures are valuable in confirming negative diagnoses, detecting false negatives on microscopy, and identifying non-*albicans* isolates.<sup>229</sup> In most patients, sporadic mild-to-moderate disease responds to short courses of treatment with topical azole or nystatin preparations. Alternatively, oral therapy with fluconazole in a single 150 mg dose, itraconazole (200 mg for 3 days), or ketoconazole (200 mg twice daily for 5 days) can be used effectively.<sup>230–233</sup> In severe cases and in persons with diabetes with poor glycemic control, a week or more of topical therapy or two sequential 150-mg doses of fluconazole given 3 days apart may be necessary to achieve an adequate clinical response.<sup>88,234</sup> Boric acid solution or gentian violet solution may also be useful in management of vulvovaginal candidiasis.

Some women develop recurrent vulvovaginal candidiasis. With the exception of persons with diabetes with poor glycemic control, these patients rarely have recognizable precipitating or

causal factors. This condition likely occurs as a result of a local immunodeficiency state that permits uncontrolled proliferation of yeast within the vagina and hence repeated clinically evident attacks.<sup>235</sup> The vast majority of recurrent infections are caused by azole-sensitive *C. albicans* even in the setting of long-term exposure to azoles.<sup>236</sup> In a minority of cases, the infection is due to non-*albicans* isolates of *Candida*. *C. glabrata* is the most common non-*albicans* species isolated from the vagina. Patients with vaginitis due to non-*albicans* species of *Candida* have significantly reduced clinical and mycologic responses to azoles.<sup>234</sup> Otherwise, the clinical syndromes caused by these organisms are generally indistinguishable from *C. albicans* infections.<sup>237</sup> Some patients develop recurrent and often chronic *C. glabrata* vaginitis unresponsive to conventional therapy.<sup>238</sup> Topical boric acid (600 mg daily for 14 days) and topical flucytosine cream are options for such cases.<sup>239,240</sup> Boric acid treatment has also been useful in cases due to *C. krusei*.<sup>241</sup> Although no definitive cure for recurrent candidal vaginitis exists, long-term maintenance regimens with oral or topical azoles can effectively control symptomatic infection in some but not all patients.<sup>235</sup> However, before initiating a prolonged course of antifungals for management of recurrent vulvovaginal candidiasis, the diagnosis should be confirmed.

## ■ Candida Balanitis

*Candida* spp. are the most common infectious cause of balanitis and account for approximately one third of all cases.<sup>67,242</sup> The lesions start as small papules and papulopustules that may slough off, leaving erythematous erosions with associated whitish scales. The infection can spread to involve the scrotum and inguinal areas. There is often pruritus and burning, particularly following sexual intercourse.<sup>243</sup> In persons with diabetes or immunosuppressed patients, extensive cutaneous invasion can occur with severe edema and ulceration.<sup>67,244</sup> The presence of refractory *Candida* balanitis may be the harbinger of HIV infection or diabetes mellitus.

Topical therapy with azole antifungals is generally effective. In a trial involving 148 patients with candidal balanitis, 91% of men were asymptomatic after 7 days, and 98% were asymptomatic after 3 weeks of treatment with topical clotrimazole (1% cream).<sup>245</sup> In an open-label study, treatment with a single 150-mg dose of fluconazole was comparable in efficacy and safety to clotrimazole cream applied topically for 7 days.<sup>246</sup>

## ■ Respiratory Tract Infection

*Candida* frequently colonizes the respiratory tract.<sup>247–251</sup> Lower respiratory tract infection is uncommon and overdiagnosed. Pneumonia may be secondary to aspiration or due to hematogenous spread and occurs in patients with malignancies with and without severe neutropenia, lung transplant recipients, and neonates.<sup>250,252,253</sup> With hematogenous spread, involvement is often observed in multiple other organs as well. In lung transplant recipients, infection can occur at the bronchial anastomotic site with dehiscence of the anastomosis.<sup>254</sup> Among very low-birth-weight neonates, infection may be acquired postnatally or antenatally due to chorioamnionitis.<sup>255,256</sup>

The radiographic manifestations of candidal pneumonia include disseminated nodules in cases due to hematogenous spread and nonspecific patchy infiltrates in endobronchial infection.<sup>250,257</sup> Isolation of even a large number of organisms on bronchoscopic specimen does not necessarily reflect infection, and the only accepted criterion for definitive diagnosis is histologic demonstration of the fungus in lung tissue. Mortality due to actual candidal pneumonia is high and may exceed 80%.<sup>250</sup> *Candida* has been reported to cause epiglottitis and laryngitis in immunocompromised patients.<sup>258–260</sup> Laryngitis can be diagnosed by fiberoptic or indirect laryngoscopy; untreated, it can lead to airway obstruction and respiratory compromise. Invasive respiratory tract candidiasis should be treated with systemic antifungals. *Candida* spp. also frequently colonize voice prostheses and can lead to early deterioration of these devices.<sup>261,262</sup> Prophylactic miconazole has been shown to decrease colonization of voice prostheses and increase device lifetime.<sup>263</sup>

## ■ Endocarditis

*Candida* spp. are the most common cause of fungal endocarditis; *C. albicans*, *C. parapsilosis*, *C. glabrata*, and *C. tropicalis* account for most cases.<sup>264,265</sup> Risks for candidal endocarditis include injection drug use, indwelling vascular devices, prosthetic cardiac valves, pre-existing valve disease, antibiotic use, and immunosuppression.<sup>266,267</sup> Prosthetic valve endocarditis typically occurs in the first year after surgery but may present years later.<sup>268</sup> The large, friable vegetations have a propensity to produce systemic emboli, and patients regularly have peripheral arterial or central nervous system embolic events.<sup>269–272</sup>

Echocardiography is an important tool in the evaluation of candidal endocarditis. Large, dense heterogeneous vegetations are typical. Transthoracic echocardiography may be adequate, but transesophageal echocardiography has superior sensitivity for prosthetic valve endocarditis and allows for optimal assessment of the valvular and paravalvular structures.<sup>269,273</sup> Owing to the high risk for devastating embolic events, poor response to medical therapy alone, and frequent recurrence, valve replacement generally is necessary.<sup>274</sup> With a combined medical and surgical approach, in-hospital survival is greater than 80%, but relapses can occur.<sup>269,275,276</sup> A commonly used initial regimen is amphotericin B with or without flucytosine. The appropriate duration of antifungal therapy after surgery is not known, but a minimum of 6 weeks and possibly much longer has been advocated.<sup>88</sup> To prevent recurrences, long-term oral antifungal therapy is frequently used. In many patients, valve replacement is not an option. The optimal management of such patients is not known, but amphotericin B followed by long-term fluconazole has been used with success.<sup>277,278</sup>

Candidal endocarditis may extend to involve the myocardium. In a series of patients with candidal endocarditis, a hyperchogenic, heterogeneous myocardial texture observed on echocardiography was associated with extensive myocardial damage at surgery.<sup>273</sup>

Candidal myocarditis occurring in the setting of disseminated candidiasis but without concurrent valvular infection has been reported. Arrhythmias and conduction abnormalities may develop as a consequence of myocardial invasion.

Candidal pericarditis is a rare disease usually seen in association with cardiothoracic surgery, disseminated candidiasis, and immunocompromise. Unexplained fever, an increasing cardiac shadow on chest roentgenogram, or development of cardiac tamponade may suggest the diagnosis. Untreated, it is uniformly fatal. Pericardiocentesis followed by operative drainage and antifungal agents is the usual treatment.<sup>279–282</sup>

Mechanical cardiac assistance has recently emerged as an option for patients with severe heart failure. Several ventricular circulatory assist devices (VADs) are currently available for support of patients while they are waiting for improvement in cardiac function or heart transplantation. Infection in the postoperative period is the most serious complication. Fungal infections associated with VADs include device-related bloodstream infections and less commonly endocarditis.<sup>283,284</sup> In addition to treatment with antifungals, removal of the device generally is necessary for clearance of the infection. Implantable defibrillators and pacemakers are increasingly employed in patients with or at risk for arrhythmia. There have been several reports of infections in such devices including endocarditis due to *C. tropicalis*, *C. glabrata*, and *C. albicans*.<sup>285–287</sup> Complete device explantation and prolonged antifungal therapy are the treatment for this complication.

## ■ Urinary Tract Infection

### EPIDEMIOLOGY

*Candida* spp. are frequent colonizers of the lower urinary tract. *C. albicans* represents approximately half of the fungal isolates in urine. Non-*albicans* species of *Candida* including *C. glabrata*, *C. tropicalis*, and *C. krusei* may also cause funguria, especially in patients previously treated with antifungal agents.<sup>288–290</sup> Of particular concern is the use of fluconazole in hospitalized patients. It has recently been suggested that indiscriminate use of fluconazole may lead to the emergence of fungal resistance. In a retrospective comparative study of patients admitted to medical and surgical intensive care units (ICUs), an emergence of *Candida* non-*albicans* tolerant to fluconazole was observed in fluconazole-treated patients. The same study also reported an increase in bacterial antibiotic resistance after fluconazole administration.<sup>291</sup>

Factors predisposing to candiduria include diabetes mellitus, urinary tract abnormalities, and malignancy.<sup>288,292</sup> Receipt of antimicrobial agents and presence of urinary tract drainage devices are important risk factors. In a case control study, development of candiduria was correlated with increasing duration of urinary catheterization (12 vs. 6 days), length of time on multiple antibiotics (16 vs. 7 days), and length of total hospitalization.<sup>293</sup> In an ICU surveillance study, candiduria developed in 22% of patients admitted for more than 7 days.<sup>294</sup> In that same study, independent risk factors for candiduria included age greater than 65 years, female sex, length of hospital stay before ICU admission, diabetes mellitus, total parenteral nutrition, mechanical ventilation, and previous antimicrobial use. In a neonatal ICU study, *Candida* spp. were identified in 42% of urinary tract infections, and more than half these patients had associated candidemia.<sup>295</sup> *C. parapsilosis* and *C. tropicalis* (25% and 13%, respectively) were the most frequent non-*albicans* species

isolated in neonates with urinary tract infections in the neonatal ICU.

### CLINICAL MANIFESTATIONS

In adults, candidemia rarely complicates candiduria.<sup>288</sup> In a study defining the risks for candidemia secondary to a urinary tract source, 88% had urinary tract abnormalities, predominantly with obstruction, and 73% had undergone urinary tract procedures before the onset of bloodstream infection.<sup>296</sup> Conversely, in patients with systemic candidiasis, hematogenous dissemination of fungus to the kidney may result in formation of cortical abscesses or obstructive intrarenal masses termed “fungal balls,” usually at the ureteropelvic junction.<sup>297,298</sup> Up to a third of neonates with candidal urinary tract infections have renal pelvis fungus balls by ultrasound studies, but these may only develop weeks after the discovery of candiduria.<sup>295,299</sup> Other complications of candidal urinary tract infection include papillary necrosis, emphysematous pyelonephritis, and emphysematous cystitis.<sup>300–303</sup>

### DIAGNOSIS

The diagnosis of fungal urinary tract infection represents a challenge to the clinician. The presence of *Candida* spp. in urine does not necessarily signify true infection and may instead merely represent colonization or even contamination of the urinary sample. The lack of specific signs and symptoms complicates the process of diagnosing fungal urinary tract infection, and some patients with infection are asymptomatic.<sup>304,305</sup> The presence of pyuria and colony counts of 10,000 to 15,000 *Candida* spp. per milliliter of urine may suggest infection; however, the predictive value of these findings when urinary catheters are in place is not known.<sup>306,307</sup> Indeed, studies in experimental renal candidiasis demonstrate that colony-forming units are not a reliable predictor of renal candidiasis.<sup>308</sup>

### TREATMENT

There are various options for management of candiduria. In the absence of an underlying chronic medical condition, the identification of *Candida* spp. in the urine may represent colonization or low-grade infection that often resolves without specific therapy or with removal of the urinary catheter. All indwelling urinary instrumentation should be removed if possible. Candiduria should be treated in symptomatic patients, low-birth-weight infants, patients with neutropenia, and persons expected to undergo urinary tract instrumentation. Antifungal therapy should be given for 7 to 14 days.<sup>88</sup> Oral fluconazole (200 mg) was compared with placebo daily for 14 days in asymptomatic or minimally symptomatic candiduric hospitalized patients. Clearance with fluconazole was significantly higher among those patients receiving fluconazole (50% vs. 29%); however, recurrences were common, and long-term candiduria rates among treated and untreated patients were similar.<sup>309</sup> Systemic amphotericin B at various doses has been used successfully in candidal urinary tract infection. In patients with intact renal function, flucytosine (25 mg/kg/d) may be an option, although resistance can develop rapidly when this agent is used as monotherapy.<sup>310,311</sup>

Amphotericin B bladder irrigation (50 mg/L over 24 hours or 50 mg/L for 7 days) has been used for candiduria. Short-term eradication rates with this type of therapy are comparable with fluconazole, but the technique is cumbersome, and patients may complain of bladder fullness.<sup>88,312</sup>

## ■ Meningitis

### CLINICAL MANIFESTATIONS

*Candida* spp. are an uncommon cause of meningitis. Infection can be secondary to hematogenous dissemination or direct inoculation. Neurosurgery, recent antibiotic therapy, and corticosteroid administration are predisposing factors. Fever, meningismus, elevated cerebrospinal fluid (CSF) pressures, and localizing neurologic signs are commonly noted. Mortality rates for patients receiving inadequate or no antifungal therapy exceed 90%. Delays in diagnosis, hypoglycorrhea, intracranial hypertension, and focal neurologic deficits are all associated with a poor prognosis.<sup>313,314</sup> In a series of patients with ventriculoperitoneal shunts, recent bacterial meningitis or neurosurgery (different from the shunt placement) and abdominal complications were associated with the development of candidal meningitis. The clinical manifestations in that series included hydrocephalus in 36%, fever in 31%, meningoencephalitis in 21%, and abdominal symptoms in 10%.<sup>315</sup> The CSF may show neutrophilic pleocytosis that is indistinguishable from bacterial meningitis or a predominance of lymphocytes. In certain circumstances, the clinical significance of *Candida* spp. isolates from cerebrospinal fluid of patients with shunts is difficult to assess. A retrospective analysis of patients with *Candida* spp. isolated from CSF following neurosurgery indicated that the diagnosis of candidal meningitis should be established by repeated cultures from both the indwelling device and lumbar puncture.<sup>316</sup> However, delay of potentially lifesaving therapy while waiting for a confirmatory CSF culture is potentially hazardous, and we do not advocate such an approach. Candidal meningitis may present as a subacute illness characterized by fever and headache of several weeks' duration and lymphocytic pleocytosis. Neurologic manifestations are diverse and can range from normal neurologic evaluation to signs of CNS infarcts or hydrocephalus.<sup>317–319</sup> Candidal infection may also present as an intense granulomatous and necrotizing basal meningitis that can lead to cranial neuropathies or basilar artery thrombosis with resultant brainstem and temporo-occipital infarction.<sup>320,321</sup>

Candidal meningoencephalitis frequently is associated with systemic candidiasis in premature neonates.<sup>322,323</sup> In a retrospective review of systemic candidiasis, more than a fifth of neonates with systemic candidiasis had candidal meningitis (0.4% of admissions to the neonatal ICU).<sup>324</sup> This complication is associated with very low birth weight and delivery at early gestational age. In a study of meningitis in very low-birth-weight (<1.5 kg) infants, *Candida* spp. were responsible for 20% of episodes.<sup>325</sup> The initial clinical features of candidal meningitis are indistinguishable from those of other causes of systemic infection in premature neonates. Analysis of CSF commonly shows hypoglycorrhachia, but pleocytosis is inconsistent, and Gram staining of CSF generally fails to detect

the agent. Therefore, normal CSF parameters do not exclude meningitis.

### TREATMENT

When infection is present, successful treatment generally requires systemic antifungal therapy and removal of the infected shunt.<sup>315</sup> Therapy with amphotericin B with and without 5-fluorocytosine has been used with success in children and adults.<sup>324,326,327</sup> In a series of 17 patients with candidal meningitis, the combination of amphotericin B and 5-fluorocytosine led to cure in 14 patients.<sup>328</sup> Because of its superior safety profile relative to conventional amphotericin B but comparable antifungal efficacy in animal models of candidal meningitis, liposomal amphotericin B is an attractive therapeutic option.<sup>329</sup> Liposomal amphotericin B was successful in five of six preterm infants with candidal meningitis.<sup>330</sup> *C. lusitanae* can be resistant to amphotericin B, and fluconazole has been used successfully in two children with meningitis due to that pathogen.<sup>331</sup>

## ■ Joint Infection

### CLINICAL MANIFESTATIONS

*Candida* spp. are an uncommon cause of infectious arthritis. Infection occurs following direct inoculation of fungus or as a result of hematogenously disseminated disease. The most commonly involved joint is the knee.<sup>332</sup> Infection has been reported following intra-articular injections into the knee of an immunocompromised man.<sup>333</sup> Cases of candidal arthritis have been described in association with prosthetic joints, solid organ transplantation, and hematologic malignancies and following the use of intravenous antibiotics and may be the first sign of disseminated candidiasis in a compromised host.<sup>334–336</sup> Deep-seated candidal infections can complicate injection drug use. In one series, osteoarticular involvement (vertebrae, costal cartilage, knees, and sacroiliac) was noted in more than a quarter of injection heroin users treated for systemic candidiasis.<sup>337</sup> Costochondral infection is a complication of disseminated candidiasis in users of brown heroin.<sup>338</sup> The clinical findings are of a mass appearing in the anterior region of the thorax. Histopathology of the lesions shows perichondritis, sometimes with associated myositis and osteomyelitis.<sup>339</sup> Nearly a fifth of hospital-acquired arthritis in the neonatal period is due to *Candida* spp.<sup>340</sup> In children, candidal arthritis typically occurs in association with disseminated candidiasis.<sup>341</sup> The arthritis is generally seen concomitant with or shortly after fungemia but in some cases may not manifest until weeks to months later.<sup>342,343</sup>

### TREATMENT

Treatment consists of aspiration of the joint, systemic antifungal therapy, and in cases of prosthetic joint infection, removal of the infected hardware if feasible.<sup>344–346</sup> Fluconazole at doses of 200 to 800 mg daily for months to years has been used successfully.<sup>347</sup> Lipid formulations of amphotericin B have been successfully used in children and adults with *Candida* arthritis.<sup>348–350</sup> Intra-articular administration of

amphotericin B has been utilized in refractory cases and may be a useful adjunct to systemic antifungal therapy.<sup>351</sup>

## ■ Osteomyelitis

### CLINICAL MANIFESTATIONS

*Candida* spp. rarely cause osteomyelitis. Similarly to candidal arthritis, infection may occur following direct inoculation of the fungus or as a result of hematogenously disseminated disease.<sup>352</sup> Candidal mediastinitis has emerged as a complication in patients who have undergone sternotomy for thoracic surgery.<sup>353</sup> Common clinical manifestations are chest wall erythema, drainage, fever, and sternal instability. In one series, the onset of infection for most patients was within 28 days of surgery, but for others it was several months after the procedure. The infections were characterized by a chronic indolent course requiring prolonged therapy with an antifungal agent. Approximately a third of the patients relapsed and required a second course of treatment.<sup>354</sup> Surgical débridement and removal of sternotomy wires often are required.

A single strain of *C. albicans* was reported to cause post-laminectomy deep-wound infections in a cluster that involved three patients. The infections were indolent and developed weeks to months after the initial procedure. The source of the outbreak was traced to a technician who had worn artificial nails.<sup>355</sup> *C. tropicalis* vertebral osteomyelitis has also been reported to have complicated epidural catheterization in a patient with diabetes.<sup>356</sup> Spondylodiscitis and vertebral osteomyelitis can occur in association with disseminated candidiasis.<sup>357,358</sup> A recent review of the published literature found *C. albicans* responsible for 62% of cases, *C. tropicalis* for 19%, and *C. glabrata* for 14%. Almost all cases involved the lower thoracic or lumbar spine. Risk factors for candidal vertebral osteomyelitis included the presence of a central venous catheter, antibiotic use, immunosuppression, and injection drug use. Most patients had with back pain for more than 1 month, highlighting the indolent yet progressive course of this infection.<sup>359</sup> Delayed-onset osteomyelitis has been reported in two patients who developed *C. tropicalis* vertebral infections 5 and 14 months after experiencing transient fungemia.<sup>360</sup>

### TREATMENT

Treatment of candidal osteomyelitis often requires a combined medical and surgical approach. Abscesses should be drained and devitalized tissue debrided.<sup>361</sup> Amphotericin B has been used with success,<sup>359,362</sup> as have prolonged courses of fluconazole.<sup>363–366</sup> The latter is an attractive option given the relative safety and oral formulation of this agent. A treatment plan consisting of surgical debridement and an initial course of amphotericin B for 2 to 3 weeks followed by fluconazole, for a total duration of therapy of 6 to 12 months has been advocated for candidal osteomyelitis.<sup>88</sup>

## ■ Endophthalmitis

### CLINICAL MANIFESTATIONS

*Candida* spp. may cause intraocular infections with devastating consequences. Endogenous candidal endophthalmitis

occurs in association with disseminated candidiasis and may be the initial manifestation of candidemia. In addition to the typical risk factors for disseminated candidiasis, endogenous endophthalmitis has been reported in the postpartum period and in association with induced abortions.<sup>367,368</sup> Patients with candidal endophthalmitis often complain of eye pain and may have blurred vision or spots in their visual fields. On examination there can be inflammation in the anterior chamber as indicated by the presence of a hypopyon. On examination of dilated pupils with an ophthalmoscope, one or more creamy-white, well-circumscribed lesions of the choroid and retina are characteristically observed. These are often accompanied by inflammatory infiltrates in the vitreous.<sup>369</sup> In endogenous endophthalmitis, the infection likely begins in the choroid and progresses anteriorly to the retinal layers.<sup>369</sup> In a rabbit model of hematogenous candidal endophthalmitis, the ocular lesions were focal chorioretinitis characterized by a combination of granulomatous and acute suppurative reactions.<sup>370</sup> In a study of enucleated globes from patients with candidal endophthalmitis, the vitreous was the primary focus of infection.<sup>371</sup>

Studies evaluating candidemic patients have reported widely varying rates for lesions consistent with candidal endophthalmitis. Recent reports have shown a decline in the percentage of cases of candidemia-associated endophthalmitis from nearly 30% in 1989 to less than 2% in 2002.<sup>372–376</sup> The reasons for the disparities in the studies are not clear but may be related to differences in the stringency of definitions of the ocular lesions of candidal endophthalmitis. Observation of the pathognomonic three-dimensional retina-based vitreal inflammatory lesion is uncommon, whereas nonspecific findings that may or may not be due candidal endophthalmitis (such as cotton wool spots, retinal hemorrhages, and Roth spots) are frequent.<sup>377</sup> Alternative explanations for the decline are the more aggressive antifungal therapies currently in use and the changing epidemiology of candidal bloodstream infections. Of note, in an experimental rabbit model of endogenous endophthalmitis, ocular tissues were found to have increased resistance to hematogenous infections with species other than *C. albicans*.<sup>378</sup> Because endogenous candidal endophthalmitis can lead to significant visual loss or blindness, it is reasonable to assess patients with disseminated candidiasis for ocular involvement by performing a funduscopic examination on pupils that have been dilated.

Infection of the cornea and the intraocular structures as a result of direct inoculation of the organism during trauma or surgery has been described.<sup>369</sup> In a series of 44 cases of post-keratoplasty candidal endophthalmitis, 40 (91%) had evidence of donor-to-host transmission of the organism.<sup>379</sup> An outbreak of postsurgical *C. parapsilosis* endophthalmitis was traced to a contaminated lot of irrigating solution.<sup>380</sup>

### TREATMENT

Treatment of intraocular candidiasis depends on the extent of infection. When infection is limited to choroiditis or very minimal endophthalmitis, systemic antifungal treatment may be effective; however, if symptoms of vitritis persist or progress, vitrectomy may be necessary.<sup>381</sup> Systemic therapy with amphotericin B or fluconazole in conjunction with vitrectomy (with or without intravitreal amphotericin B) has

been used successfully in cases of advanced endogenous *Candida* endophthalmitis.<sup>382,383</sup> In one reported series, success was achieved following the administration of oral fluconazole (100 to 200 mg/d) for approximately 2 months.<sup>384</sup> In that report, four patients were also successfully treated with pars plana vitrectomy for moderate-to-severe vitreitis. In a series of intravenous brown heroin users with *C. albicans* endophthalmitis, favorable responses without complications were seen in all seven patients who underwent early vitrectomy (within 1 week) after the diagnosis of vitreitis. In that same series, two of three patients who underwent late vitrectomy developed blindness or scotoma. Blindness was also described in two patients with vitreitis who did not undergo vitrectomy.<sup>385</sup> Regardless of the therapy used, final visual acuity outcome depends most on the site of initial choroiditis, such that if the macula is spared and preretinal membranes can be effectively removed, visual acuity outcome can be good.<sup>381</sup>

## ■ Intra-abdominal Infections

Candidal peritonitis is most commonly seen as a complication of continuous ambulatory peritoneal dialysis (CAPD) or as a consequence of bowel injury. Rarely, spontaneous infections occur in association with chronic liver failure and ascites. CAPD has emerged as an acceptable form of renal replacement therapy in some developing countries.<sup>386,387</sup> In several series involving more than 2600 episodes of CAPD-associated peritonitis, 2.5% to 6% of cases were due to *Candida* spp.<sup>388–393</sup> Infecting organisms included *C. albicans*, *C. parapsilosis*, *C. tropicalis*, and *C. guilliermondii*. Risk factors for the development of candidal peritonitis include frequent recurrences of bacterial peritonitis and antibiotic exposure.<sup>390–393</sup> Clusters of candidal CAPD peritonitis have been described. An outbreak of *C. tropicalis* peritonitis was traced to infected water baths for several patients.<sup>394</sup> Initial clinical findings include abdominal pain and fever. The dialysate is cloudy in appearance, and fluid white cell count is typically elevated with a predominance of neutrophils.<sup>395,396</sup> Treatment of CAPD-associated candidal peritonitis with systemic antifungals is rarely adequate by itself. Cure rates with fluconazole alone are approximately 10%, and resolution of infection usually depends on removal of the infected catheter.<sup>392,397,398</sup> Failure to remove the catheter has been associated with increased mortality.<sup>399</sup> In a large cohort of children, *Candida* spp. accounted for approximately 2% of CAPD-associated peritonitis. As in adults, successful therapy of CAPD-associated candidal peritonitis in the pediatric age group generally requires a combination of antifungal therapy and dialysis catheter removal.<sup>400</sup>

*Candida* spp. may be isolated from the peritoneal fluid of patients with spontaneous perforation or a surgical opening of the gastrointestinal tract and rarely in association with appendicitis.<sup>401,402</sup> The presence of *Candida* spp. in the peritoneum, however, does not necessarily indicate infection. In a series of patients with *Candida* spp. isolated from the peritoneum, less than 40% had evidence of infection (intra-abdominal abscess or peritonitis).<sup>403</sup> In the neonatal population, *Candida* spp. may be seen at the site of intestinal perforation (candidal enteritis of the newborn) or in the peritoneum in necrotizing

enterocolitis.<sup>402,404–407</sup> Peritonitis caused by *Candida* spp. has been described in patients with decompensated liver disease and ascites. The infection may be spontaneous in origin or may reflect gastrointestinal perforation.<sup>408–410</sup> Pancreatic abscesses due to *Candida* spp. can occur in association with pancreatitis, with pancreatic pseudocysts, and as a complication of endoscopic retrograde choledochopancreatography (ERCP).<sup>411–413</sup>

## ■ Chronic Disseminated Candidiasis

The syndrome of chronic disseminated candidiasis (CDC) has emerged as a problem in neutropenic patients, particularly those receiving therapy for acute leukemia. In a series of 500 adult patients with acute leukemia who received chemotherapy, CDC was diagnosed in 37 (7.4%).<sup>414</sup> This condition is often referred to as hepatosplenic candidiasis, but the term chronic disseminated candidiasis is more accurate, since multiple organs, including the lungs and kidneys, can be involved. The diagnosis is typically made after resolution of the neutropenia. Clinical and laboratory features include fever, abdominal pain, hepatomegaly, and elevated serum alkaline phosphatase levels. In a series of patients with CDC, abdominal ultrasonography was positive in 96% of patients,<sup>27,28</sup> abdominal computed tomography (CT) scan was positive in 21/21 patients (100%), and liver biopsy was positive in 10/15 patients (67%).<sup>415</sup> CT shows low-density lesions of the liver, spleen, and kidneys; hepatomegaly; and hepatosplenomegaly.<sup>416</sup> Magnetic resonance imaging (MRI) has emerged as a technique with high diagnostic accuracy and can help in distinguishing acute, subacute treated, and chronic healed CDC.<sup>417–419</sup> Laparoscopy typically shows yellowish nodules, and the diagnosis can be established by targeting these macroscopic lesions for biopsy.<sup>420</sup> Histopathologic studies may show large granulomas with yeasts and pseudohyphae.<sup>421</sup> Systemic treatment with amphotericin B, caspofungin, or fluconazole has been successful but needs to be prolonged, sometimes for months, until resolution of the lesions.<sup>414,417,422–424</sup> The presence of CDC does not preclude further chemotherapy and does not constitute a contraindication to marrow transplantation provided that antifungal therapy is continued.<sup>425,426</sup>

## ■ Bloodstream Infections

### EPIDEMIOLOGY AND PATHOGENESIS

*Candida* spp. constitute an important pathogen in bloodstream infections. The vast majority of cases of candidemia occur in hospitalized patients, and approximately 25% to 50% are associated with ICUs.<sup>427,428</sup> Such units in particular have numerous risk factors and increased incidence of nosocomial fungal infections. In an analysis of more than 30,000 fungal infections, the highest number of nosocomial fungal infections/1000 discharges was reported from the burn/trauma service.<sup>429</sup> As a whole, *Candida* spp. are the fourth most common cause of nosocomial bloodstream infections in children and adults.<sup>304,430</sup> Crude and attributable mortality rates of approximately 60% and 40%, respectively, have been reported for nosocomial candidemia.<sup>431,432</sup>

*C. albicans* constitutes, by far, the most commonly isolated species in nosocomial candidemia, but nearly half of cases are now due to species other than *C. albicans*.<sup>41,433</sup> There has been a recent increase of clusters and outbreaks of bloodstream infections due to *Candida* spp. in high-risk settings such as neonatal and surgical ICUs.<sup>434–439</sup> The high rate of fungemia in this population is associated with several factors. Transmission of yeast between patients and health-care workers can occur via unwashed hands of hospital personnel working in ICUs.<sup>437</sup> Autoinfection after previous colonization with *Candida* spp. of gastrointestinal tract origin has also been demonstrated.<sup>440</sup> Invasive diagnostic and therapeutic interventions, such as percutaneous intravenous lines, drains, and intracranial pressure monitors that breach the protective layer of the dermis and serve as conduits for pathogenic organisms to enter the bloodstream are also likely contributors to the development of candidemia.

Other factors linked to the increased rate of *Candida* bloodstream infections rely on the use of broad-spectrum antibiotics. The empiric treatment of critically ill patients with sepsis is generally prescribed before the results of the cultures are known. In an observational study, the increased use of cephalosporins in an ICU was associated with a rise in candidemia.<sup>441</sup> Changes in the gut microflora associated with broad-spectrum antibiotics may play a role in bacterial translocation and overgrowth of *Candida* in the intestinal lumen with further vascular invasion.

Propofol in an emulsion preparation (Diprivan) is a lipid-based anesthetic agent that has been implicated in several outbreaks of postoperative infections due to extrinsic transmission by anesthesia staff.<sup>442</sup> The first outbreak occurred in 1990 when the Centers for Disease Control received reports of five outbreaks of postoperative bloodstream infection or acute febrile illness that involved *Candida* spp. In one cluster, four patients developed endogenous *Candida* endophthalmitis.<sup>443</sup>

Pressure-monitoring devices (transducers) are used regularly in critically ill patients for hemodynamic monitoring and can provide a portal of entry for systemic infections. Intravascular pressure monitor devices used in conjunction with arterial catheters have been implicated in several outbreaks of nosocomial bacterial and fungal bloodstream infections. Several outbreaks of infections due to the contamination of pressure monitoring with *Candida* have been reported.<sup>444–446</sup> The mechanism of infection was attributed to the lack of proper disinfection of reusable transducers, particularly the chamber domes, which served as a reservoir for the organism. No further outbreaks have been reported since the use of disposable systems.

Nosocomial infections result in considerable morbidity and mortality among neonates, especially those in neonatal ICUs (NICUs). The incidence of nosocomial *Candida* infections, including outbreaks, has been increasing.<sup>434–436,439,447–450</sup> Traditionally it has been thought that the acquisition of *C. albicans* by neonates occurs via mother-neonate transmission or from endogenous flora of colonized patients.<sup>451</sup> Recent epidemiologic studies, assisted by molecular typing, have demonstrated that exogenous infections due to the administration of contaminated fluids, cross-infection, and the colonized hands of health-care workers are also important contributors for the transmission of *Candida* spp. in NICUs.<sup>435,436,438,439,452</sup>

Risk factors for fungal bloodstream infections in neonates include prematurity, especially very low-birth-weight neonates; use of broad-spectrum antibiotics; prolonged mechanical ventilation; coagulopathy; parenteral nutrition; catheterization of central vessels; H<sub>2</sub> blocker therapy; and prolonged hospitalization in NICUs.<sup>453</sup> A recent case-control study characterized the clinical aspects of 49 neonates with *Candida* bloodstream infections in the NICU.<sup>454</sup> The most common manifestation of *Candida* spp. bloodstream infections identified in neonates is abdominal distention (49%), followed by poor peripheral perfusion (46%) and fever (43%). Among *Candida* spp. pathogenic to humans, *C. albicans* remains the species most frequently associated with neonatal bloodstream infections in the NICU; however, recent trends toward an increase in non-*albicans* species have been reported.<sup>439,454,455</sup> Recent reports suggest an increasing number of infections attributable to *C. parapsilosis* in NICUs. In general, clinical reports suggest that *C. parapsilosis* is a less virulent organism than *C. albicans*. However, a comparative study of bloodstream infections due to these organisms in neonates demonstrated no significant difference in fungal eradication rate, and the overall mortality rate was comparable for both groups.<sup>456,457</sup> The increased morbidity of candidal bloodstream infections in neonates in NICUs mandates a high index of suspicion for this infectious complication and institution of early antifungal treatment. New and more effective strategies must be developed for prevention of transmission in the intensive care setting.

## DIAGNOSIS

Blood culture is the main test for establishing the diagnosis of candidal bloodstream infection. However, such cultures are often negative despite disseminated disease. In an autopsy controlled study of the sensitivity of blood cultures for detection of tissue-proved invasive candidiasis, *Candida* spp. were isolated from blood in 11 of 19 patients (58%) with disseminated infection.<sup>458</sup> All *Candida* spp. isolated from blood cultures should be considered significant unless proved otherwise.<sup>13</sup> Since many cases of invasive candidiasis are missed by standard microbiologic methods, nonculture-based diagnostic tests are urgently needed. Such assays, including tests for D-arabinitol, mannans, glucans, anticandidal antibodies, and polymerase chain reaction (PCR) are in development.

## TREATMENT

Fungal infections, particularly invasive candidiasis, are among the most serious infections acquired by critically ill patients requiring intensive care. Comorbid conditions and the increased severity of illness in patients hospitalized in ICUs mandate a high index of suspicion and early initiation of antifungal therapy for improved patient outcome. As described earlier, *Candida* spp. cause a broad range of invasive infections that require different therapeutic strategies. In addition, the choice of therapy will be directed by weighing the greater activity of amphotericin B for azole-resistant *Candida* spp. against the lesser toxicity of the azole and echinocandin antifungal agents. Treatment of invasive candidiasis due to non-*albicans* species may be guided by in vitro susceptibility testing, particularly in those patients previously treated with

azoles in whom acquired antifungal resistance should be considered.

Among the currently available antifungal drugs for the treatment of fungal infections, amphotericin B remains the standard agent for the treatment of *Candida* infections. Lipid formulations of amphotericin B have substantial advantage over amphotericin B deoxycholate in that they are less nephrotoxic and appear to be at least as active as the parent compound. Three lipid formulations of amphotericin B have been approved for use in humans: amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion (ABCD), and liposomal amphotericin B (LAMB, AmBisome). Only ABLC and LAMB have been approved for use in proven candidiasis for patients intolerant or refractory to amphotericin B. The optimal dose of these formulations for severe *Candida* infections is unclear; however, doses of 3 to 5 mg/kg appear to be suitable for treatment of serious infections. Amphotericin B at 0.5 to 0.6 mg/kg and fluconazole at 400 mg/d have similar efficacy in treating hematogenous candidiasis.<sup>459</sup>

Choice of therapy will depend on patient status and antifungal susceptibility pattern of the infecting isolate. Recommendations have been recently published by the Infectious Diseases Society of America.<sup>88</sup> In stable patients who have not received previous therapy with an azole, treatment with fluconazole at 6 mg/kg/d or more seems to be appropriate.<sup>88,460</sup> However, in clinically unstable patients infected with an unknown species, amphotericin B at 0.7 mg/kg/d or more or a lipid formulation of amphotericin B would be the drug of choice owing to its broader spectrum. Neonates with disseminated candidiasis are usually treated with amphotericin B. Infections due to *C. albicans*, *C. tropicalis*, and *C. parapsilosis* may be treated with either amphotericin B (0.6 mg/kg/d) or fluconazole ( $\geq 6$  mg/kg/d). Patients with *C. glabrata* infections are usually administered amphotericin B at 0.7 mg/kg/d or more as initial therapy. If the infecting isolate is identified as *C. krusei*, amphotericin B at 1.0 mg/kg/d or a lipid formulation of amphotericin B is the treatment of choice. For infections due to *C. lusitanae*, fluconazole at 6 mg/kg/d is the preferred therapy given the resistance pattern of some isolates of *C. lusitanae* to amphotericin B. Treatment of candidemia should be continued for 2 weeks after the last positive blood culture and clinical resolution of infection. Caspofungin (70 mg on the first day followed by 50 mg/d) has comparable efficacy and a superior safety profile when compared with conventional amphotericin B (0.6 to 1.0 mg/kg/d) for the primary treatment of invasive candidiasis.<sup>461</sup> Therefore, although experience with this agent is limited, it appears to be a reasonable choice for therapy in adults.

Treatment of hematogenous candidiasis should include removal of all existing central venous catheters whenever feasible. In a study of candidal bloodstream infection, the mortality rate of patients with catheter-related candidemia in whom the catheters were retained was significantly higher than that of patients in whom the catheters were removed (41% vs. 21%,  $P < 0.001$ ).<sup>462</sup> In another study, removal of the catheter was associated with more rapid clearance of the bloodstream (from  $5.6 \pm 0.8$  days to  $2.6 \pm 0.5$  days ( $P < 0.001$ )).<sup>463</sup> In a study of neonates, early removal of a central venous catheter (within 3 days of the first positive blood culture) was associated with significant reduction in the duration of

candidemia (median, 3 vs. 6 days) and mortality (2% vs. 19%).<sup>464</sup> For patients in whom the vascular catheter cannot be removed, salvage of the device may be attempted with medical therapy alone. Experimental data and limited clinical reports suggest that in selected cases treatment of infected catheters by instillation of antibiotic lock solutions containing amphotericin may be an option.<sup>88,465–467</sup>

## PREVENTION

Prevention of infection depends on meticulous hygiene and infection control measures. Additionally the role of prophylactic antifungal therapy has emerged as an issue in patients at high risk for invasive candidal infection. In a study of bone marrow transplant recipients, fluconazole (400 mg/d) administered prophylactically from the start of the conditioning regimen until resolution of neutropenia was compared with placebo. The drug was well tolerated and prevented infection with all strains of *Candida* except *C. krusei*, but there was no significant difference in overall mortality between the two groups.<sup>468</sup> Fluconazole prophylaxis was also beneficial in patients with acute myeloid leukemia who were undergoing intensive induction therapy.<sup>469</sup> Antifungal prophylaxis may have a role in solid organ transplant recipients. In a study of liver transplant recipients, fluconazole (400 mg/d) administered until 10 weeks after transplantation was compared with placebo. Fluconazole prevented infection by most *Candida* spp. except *C. glabrata*, but overall mortality was similar in both groups.<sup>470</sup> The safety and efficacy of antifungal prophylaxis to prevent candidal bloodstream infection among high-risk adults in the ICU are not known. Antifungal prophylaxis may also have a role in very low-birth-weight neonates. Prophylactic fluconazole for 6 weeks was superior to placebo in preventing fungal colonization and invasive infection when used in preterm infants weighing less than 1000 g. Ultimately, however, the usefulness of any prophylactic regimen depends on the prevalence of candidal infections in a given environment and must be individualized for each setting.

# Entomophthoramy- cosis, Lobomycosis, Rhinosporidiosis, and Sporotrichosis

DUANE R. HOSPENTHAL  
JOHN E. BENNETT

## INTRODUCTION

The four diseases reviewed in this chapter—entomophthoramycosis, lobomycosis, rhinosporidiosis, and sporotrichosis—are either restricted to, or occur predominantly in, the tropical regions of the world. All present most often as lesions of the skin or mucous membranes. Though all were previously believed to be mycoses, the etiologic agent of rhinosporidiosis has recently been shown to be more closely related to a group of protistan parasites. Entomophthoramycosis presents as a painless, firm, circumscribed subcutaneous mass, either involving the nose and surrounding face or a single area of the skin elsewhere. The overlying skin is usually normal, but may be reddened and shiny. Lobomycosis presents as a single, sharply circumscribed, painless verrucous cutaneous papule or plaque. Rhinosporidiosis commonly presents as a single, soft, fleshy polyp of the nasal mucosa or palpebral conjunctiva. Sporotrichosis most often presents as one or more red nodules on the exposed skin that may ulcerate or have intermittent serosanguineous drainage.

## ■ Entomophthoramycosis

Diseases caused by species of the genera *Basidiobolus* and *Conidiobolus* are recognized by many names. Together, they are most often denoted by the term *entomophthoramycosis*, reflecting the order Entomophthorales to which they belong. Alternatively, they are grouped along with other pathogens of their class Zygomycetes and called zygomycoses. Individually, disease caused by *Basidiobolus ranarum* is termed basidiobolomycosis. *Conidiobolus coronatus* infection is called conidiobolomycosis.

## EPIDEMIOLOGY

Basidiobolomycosis is a subcutaneous infection that predominantly affects children and adolescents and has its highest prevalence in tropical Africa and Southeast Asia. It was first reported by Joe and colleagues<sup>1</sup> in 1956 in three

Indonesian children. In one of the largest series, Mugerwa<sup>2</sup> reported 80 cases of basidiobolomycosis from Uganda. A 5:3 male-to-female predominance was noted. Although disease was observed in persons from ages 1 to 58 years, 76% of those affected were under 10 years of age (and almost half were under 5 years old). Conidiobolomycosis is a submucosal rhinosinusitis occurring most frequently in adults in the tropics (especially in the tropical rain forests of West Africa). It was first described by Emmons and Bridges<sup>3</sup> in 1961 as causing nasal polyps in horses. The first human case was reported in 1965 by Bras and associates.<sup>4</sup> Until 1992, approximately 100 human cases had been reported.<sup>5</sup> *B. ranarum* and *C. coronatus* are found in nature in soil, decaying vegetation, and in the intestinal tracts of amphibians, reptiles, and other animals.<sup>6,7</sup> Although these fungi can be recovered throughout the world, they favor warm, humid climates. *C. coronatus* has been shown to require 95% humidity to produce conidia, with maximal conidiation occurring at 100% humidity.<sup>8</sup>

## DISEASES

While the fungi causing these diseases and their respective clinical manifestations differ, the pathologic findings in the two entomophthoramycoses are similar. Both cause indolent infection with granulomatous changes in the skin and subcutaneous tissues without bony or systemic involvement. Basidiobolomycosis presents with a solitary, asymptomatic, circumscribed, hard, subcutaneous mass usually located in the buttock or extremities. Sixty-five percent of patients in one report had disease confined to either the buttock (28 of 75) or thigh (21 of 75).<sup>2</sup> These lesions do not commonly involve muscle and may not involve overlying skin.

Conidiobolomycosis most frequently begins in the submucosa of the nose, spreading to involve bilateral skin of the nasal region, the paranasal sinuses, and the pharynx. The skin is firmly attached to underlying subcutaneous tissues and may appear normal, or reddened and shiny. Conidiobolomycosis may be asymptomatic or may be diagnosed after symptoms of nasal obstruction, rhinorrhea, or epistaxis. Bacterial sinusitis from obstruction of drainage may also lead to presentation. Entomophthoramycosis is most often slowly progressive, resulting only in cosmetic disfigurement. Occasionally, long-standing infection may be complicated by obstruction of the lymphatics in basidiobolomycosis or the facial structures in conidiobolomycosis. Recently, cases of basidiobolomycosis affecting and confined to the gastrointestinal tract have been increasingly reported, including from Brazil,<sup>9</sup> the United States<sup>10,11</sup> and Kuwait.<sup>12</sup> A handful of disseminated cases of disease caused by *Conidiobolus* species (including one due to *C. coronatus*<sup>13</sup>) have been reported.<sup>14–17</sup> Disease caused by *C. coronatus* similar to that in humans has been seen in sheep, llamas,<sup>18</sup> horses, mules, dolphins, and a chimpanzee. Disease caused by *Conidiobolus incongruus* has been associated with the deaths of 700 sheep in an outbreak in Australia.<sup>19,20</sup> *B. ranarum* also causes granulomatous skin lesions in horses.

## PATHOGENESIS AND IMMUNITY

Little is known about the pathogenesis of these diseases. Both *Basidiobolus* and *Conidiobolus* possess the ability to grow in vitro at 37°C and have been shown to elicit specific antibodies

in humans and animals. Their described in vitro production of extracellular proteases and lipases has been postulated to play a role in the limited virulence of these organisms.<sup>21,22</sup>

## DIAGNOSIS

Diagnosis of entomophthoromycosis is based on biopsy with microscopic examination of tissue and culture of the etiologic agent. Clinically, basidiobolomycosis can be confused with soft-tissue sarcoma. Fibrosing panniculitis and bacterial cellulitis are almost always painful and are thus not difficult to differentiate from this disease. On microscopic examination of biopsy material, both of these organisms are seen as short, aseptate, or sparsely septated wide hyphae with surrounding eosinophilic material in subcutaneous granulomas. The surrounding material stains strongly with periodic acid–Schiff (PAS) stain in what is referred to as the Splendore-Hoepli phenomenon (see explanation under Sporotrichosis).<sup>23</sup> In addition to observation in tissue sections, these fungal elements may be seen by direct observation in potassium hydroxide wet mounts. Definitive diagnosis is made by culture. Culture of these organisms is usually done on Sabouraud glucose agar containing antibacterial antibiotics at 25°C to 30°C. Both genera grow well at temperatures of 25°C to 37°C, producing mycelial growth in several days. Conidia that are forcibly discharged are characteristic of the Entomophthorales. In cultures of *B. ranarum* and *C. coronatus*, these conidia may be seen on the covers of Petri plates as the cultures mature. *B. ranarum* produces wide hyphae (8 to 20 µm), which become progressively more septate with time. Forcibly discharged conidia, adhesive conidia, and beaked thick-walled zygosporangia are produced by this species. *C. coronatus* produces phototropic discharged conidia, villose conidia, but no zygosporangia. No commercially available serologic tests are available to diagnose the entomophthoromycoses. Studies have shown that the genera induce production of a specific antibody response, which may be shown by immunodiffusion. Studies using *B. ranarum* have shown precipitin bands of antigens specific to the species as well as one shared with *C. coronatus* and *Pythium insidiosum*.<sup>24,25</sup>

## TREATMENT

Basidiobolomycosis and conidiobolomycosis differ in their response to therapy. Limited in vitro susceptibility data have shown high MICs for amphotericin B and flucytosine for both species, obtainable MICs for the azoles against *Basidiobolus*, and mixed results for *Conidiobolus* with the azole antifungals.<sup>26,27</sup> Both have responded to extended therapy with potassium iodide (6 to 12 months; Table 84-1). In basidiobolomycosis, successful therapy with ketoconazole or trimethoprim-sulfamethoxazole<sup>28</sup> has been reported. Spontaneous resolution is occasionally seen in both diseases, but surgical excision is rarely curative in either. No consistently effective therapy for conidiobolomycosis has yet been found. Mixed results have been reported with therapies including iodide, amphotericin B, trimethoprim-sulfamethoxazole, ketoconazole, and surgery.<sup>5,29</sup> Both successful and unsuccessful results of therapy with ketoconazole have been reported.<sup>30–32</sup> Improvement of disease with fluconazole therapy has been reported in two patients.<sup>33,34</sup> Response to combination therapy

**Table 84-1** Therapy of Entomophthoromycosis, Lobomycosis, Rhinosporidiosis, and Sporotrichosis

Disease	Primary Therapy	Alternative Therapy
Entomophthoromycosis		
Basidiobolomycosis	SSKI	Ketoconazole
Conidiobolomycosis	SSKI	Ketoconazole
Lobomycosis	Surgery	None
Rhinosporidiosis	Surgery	None
Sporotrichosis		
Cutaneous	SSKI or itraconazole	Fluconazole or heat*
Osteoarticular	Amphotericin B or itraconazole	
Pulmonary	Surgery +/- amphotericin B or itraconazole	Amphotericin B, itraconazole
Disseminated	Amphotericin B	Itraconazole

SSKI, saturated solution of potassium iodide.

\*For cutaneous plaque lesions.

with fluconazole and itraconazole has been reported in one person.<sup>35</sup>

## Lobomycosis

Lobomycosis (Lobo's disease, keloidal blastomycosis) is a chronic cutaneous disease found only in Central and South America and is caused by the fungal pathogen *Lacazia loboi*. First described by Lobo in 1931,<sup>36</sup> the disease was initially thought to be an atypical presentation of paracoccidioidomycosis. In describing the second reported case in 1938,<sup>37</sup> Fialho thought the histopathology of these first two cases was clearly different from paracoccidioidomycosis, and coined the term *Lobo's disease* to describe the new entity. Since that time, over 300 cases have been described.<sup>38</sup> The etiologic agent of lobomycosis, previously denoted *Loboa loboi* or *Paracoccidioides loboi*, has been renamed *Lacazia loboi*.<sup>39</sup> Although a recent mouse foot-pad model has been developed to study this disease,<sup>40,41</sup> our inability to isolate and cultivate the organism from patients and the environment using standard methods has greatly limited our understanding of its habitat and life cycle.

## EPIDEMIOLOGY

Epidemiologically, the disease is limited to the tropical and subtropical forests of Central and South America, with the greatest number of cases among the Cayabi tribe of Brazil. In total, 57 cases of lobomycosis have been reported in the Cayabi.<sup>38</sup> Interestingly though, no disease has been noted in those members of the tribe who were born since the tribe relocated to a different region of Brazil. This disease shows no predilection for race, sex, or age, but is seen in persons who work outdoors in rural, hot, humid areas. Cutaneous trauma is thought to be the initiating event in this disease, but cases following insect stings have been reported. Apart from

human disease, lobomycosis has only been seen to occur naturally in dolphins. A single zoonotic case has been reported, occurring in the attendant of a dolphin also diagnosed with the disease.<sup>42</sup>

## DISEASE

Lobomycosis is a chronic granulomatous disease of the dermis which produces plaques, nodules, verrucoid lesions, or ulcerated lesions. Beginning as a well-circumscribed papule, the disease is otherwise asymptomatic and spreads by local extension, autoinoculation, and possibly via the lymphatic system. Common sites of initial lesions include the extremities and the ears. The lesions grow slowly for years to decades before most patients seek medical attention. Typical features include indurated lesions with sharp, lobulated margins, which are painless and not attached to underlying structures. The skin is usually shiny, discolored, and atrophic. Complications of disease, including ulceration and bacterial superinfection, are rare. Squamous cell carcinoma has been reported in extremely chronic lesions in three patients.<sup>43</sup>

## DIAGNOSIS

Diagnosis is made by the direct observation of *L. loboi* in lesional biopsy material. Clinically, the lesions of lobomycosis may be similar to those seen in chromoblastomycosis, paracoccidioidomycosis, leishmaniasis, mycosis fungoides, dermatofibrosarcoma protuberans, Kaposi's sarcoma, and squamous cell carcinoma. Microscopically, the dermis is replaced by histiocytic granulomas that contain organisms and remnants of organisms. Disease does not extend deeper than the subcutaneous tissue. Globose to elliptic or lemon-shaped cells approximately 10 µm in diameter strung together by small tubular connections (resembling a pearl necklace) are typically seen in tissue. The cell walls of the organisms may be quite thick (up to 1 µm). These may be seen with standard hematoxylin and eosin (H&E) stain, but are often better appreciated with PAS or Gomori's methenamine silver (GMS) stain. Direct observation of biopsy material mounted in KOH may also yield the diagnosis.

## TREATMENT

The only effective therapy is early wide excision of lesions. Surgical removal of chronic lesions can be effective, but recurrence is common. Medical therapy has been ineffective in the treatment of lobomycosis. The overall prognosis in this disease is very good as the mycosis spreads very slowly and is associated with limited morbidity.

## ■ Rhinosporidiosis

Rhinosporidiosis is a chronic granulomatous submucosal or subcutaneous disease seen most commonly in India and Sri Lanka. This disease was first described in an Argentinean man by Seeber in 1900.<sup>44</sup> In 1923, Ashworth<sup>45</sup> produced a classic monograph on the morphology and clinical manifestations of rhinosporidiosis. As with *L. loboi*, study of this disease has been hampered by our inability to reproducibly culture or

maintain it in the laboratory. Recent studies of 18S small-subunit ribosomal DNA sequences of the organism have placed *Rhinosporidium seeberi* into a novel group of aquatic protistan parasites.<sup>46,47</sup>

## EPIDEMIOLOGY

The ecological niche of the organism is not known, although disease has been associated with bathing in stagnant water, river diving, and rice paddy cultivation. Disease has been reported worldwide, with areas of increased incidence in India, Sri Lanka, South America, and Africa. Indigenous cases have been reported from many countries,<sup>48–50</sup> although the greatest numbers of cases outside India and Sri Lanka are in persons originally from those countries. Disease occurs most frequently in children and young adults (ages 15 to 40 years) with a male predominance. A 4:1 male-to-female ratio was noted in one study of 255 cases.<sup>51</sup> In addition to human disease, infection in the nasal passages of cats, cattle, dogs, goats, horses, mules, ducks, parrots, and swan has been described.

## DISEASE

Disease most frequently presents as friable polypoid nodules in the nose, nasopharynx, or conjunctiva. Approximately 70% of rhinosporidiosis is limited to the nasal mucous membranes, with the conjunctiva being the next most common site of infection. Submucosal lesions of the lacrimal sac, larynx, trachea, ear, vagina, and rectum, as well as subcutaneous lesions of the penis,<sup>52</sup> scrotum, face, scalp, and other areas of the body have been described. Rarely, isolated bone lesions<sup>53</sup> and disseminated cutaneous lesions<sup>54–56</sup> have been reported. Presenting symptoms are usually those of unilateral nasal obstruction or epistaxis. Cough secondary to postnasal discharge can occur. Occasionally the disease can be complicated by bacterial sinusitis if sinus drainage becomes obstructed. Localized disease is the rule, with disseminated disease of deep organs and tissues noted in only three of several thousand reported cases.<sup>57</sup>

## PATHOGENESIS AND IMMUNITY

Rhinosporidiosis has been shown in limited studies to elicit a cell-mediated immune response. Immunohistochemistry has shown that the cell infiltration in human infection includes suppressor lymphocytes and natural killer cells; lymphoproliferation assays have revealed the development of specific immune suppression to *R. seeberi*.<sup>58</sup> Specific delayed-type hypersensitivity has been demonstrated in a mouse foot-pad model.<sup>59</sup>

## DIAGNOSIS

Rhinosporidiosis may be suspected in subjects with polypoid lesions that contain white dots on close inspection. Nasal polyps need to be differentiated from those seen in allergic disease. Vaginal and penile lesions may resemble condylomata, while rectal lesions may mimic prolapsed internal hemorrhoids. Diagnosis is based on the direct observation of the organism in tissue. Culture and serology are not currently available. Microscopic examination can be done with KOH mounts of macerated tissue or stained histologic sections of lesions.

Direct observation of biopsy material may reveal white subepithelial dots, which are the large sporangia of *R. seeberi*. These sporangia, which may contain thousands of endospores, can grow to diameters of 350  $\mu\text{m}$ . Though similar in structure to the spherules of *Coccidioides immitis*, both the sporangia and endospores are larger in rhinosporidiosis. The sporangium wall of *R. seeberi* is also much thicker. Structures of the organism stain well with GMS and PAS stains, but its size allows the diagnosis to be made easily with standard H&E staining. Histopathologically, an inflammatory response with neutrophils, lymphocytes, plasma cells, and multinucleated giant cells is seen in the submucosa underlying normal columnar or squamous epithelium. Papillomatous hyperplasia and increased vascularity may also be seen in these lesions.

## TREATMENT

Surgical excision is the only known effective therapy for rhinosporidiosis. Recurrence is common following surgical excision and has led to the practice of wide surgical excision of lesions followed by electrocoagulation of their bases. Medical therapy has not proved effective, although reports of success with dapson 100 mg/day for one year have been published.<sup>60</sup>

## ■ Sporotrichosis

Sporotrichosis is a chronic, usually cutaneous, fungal infection caused by *Sporothrix schenckii*. Though disease is most commonly limited to cutaneous and subcutaneous tissue, osteoarticular, pulmonary, and other deep infections can occur. Cutaneous sporotrichosis is caused by inoculation during minor trauma, although the incident is often not remembered. Extracutaneous infection is thought to be initiated via inhalation of the organism with or without dissemination. Sporotrichosis was first described in 1898 by Schenck for whom the organism was later named.<sup>61</sup> Study of sporotrichosis in France by Beurmann and Gougerot in the early twentieth century produced the monograph *Les Sporotrichoses*,<sup>62</sup> and led to the use of potassium iodide as an effective therapy for this mycosis.

## AGENT

*S. schenckii* is a temperature-dependent dimorphic fungus which is found in the environment, usually on living or decaying plants. In this niche and in culture at room temperature, *S. schenckii* is a filamentous fungus (mold). In host tissue and at 37°C in culture, the morphology of the organism is that of a yeast.

## EPIDEMIOLOGY

Though worldwide in its distribution, sporotrichosis is most commonly seen in tropical and subtropical climates. This disease usually has a focal distribution, occurring endemically and in small epidemics in temperate and tropical environments. In clustered cases it has been associated with the distribution of sphagnum moss and with mine timbers. The common cutaneous form is usually seen in young adults, without predilection for sex or race. Infection occurs in immunocompetent persons, often those who work outdoors

in contact with vegetation or soil. An epidemiologic survey employing skin testing has shown a higher incidence of positive delayed cutaneous hypersensitivity in plant nursery workers than in hospitalized patients or prisoners (32.3% vs. 11.2%).<sup>63</sup> Pulmonary disease has a male predominance and an association with alcohol dependence. Of the 66 known cases in the world in 1986,<sup>64</sup> the male-to-female ratio was 6:1. Thirty of 51 of these cases were seen in patients with impairment of host defenses, with 19 associated with alcohol dependence. Disseminated disease is more common in patients who are immunosuppressed.<sup>65–67</sup> In the unimpaired host, the incidence of disseminated disease is thought to be quite low. Lurie<sup>68</sup> found only five cases of disseminated disease in over 3000 cases (incidence of 0.2%) of sporotrichosis in the study of the South African mine outbreak. Sporotrichosis has also been shown to occur in armadillos, birds, camels, cats, cattle, dogs, dolphins, goats, horses, mules, and rats.<sup>69</sup>

## DISEASE

Cutaneous disease begins as a relatively painless papule, which enlarges slowly and then drains spontaneously. Infection can remain localized or may spread slowly via the lymphatic system to involve proximal sites on an extremity. Although infection may reach the axillary or inguinal lymph nodes, hematogenous dissemination from skin inoculation has not been described. Rarely, lesions may also be solitary and fixed, presenting as plaques which wax and wane for years without resolution. Although minor (often insignificant) trauma is thought to be the common mode by which cutaneous disease is initiated, disease following or associated with insect stings, fish handling, bites or scratches of dogs, cats, parrots, and wild rodents has been reported. Of these other potential sources of infection, zoonotic transmission from cats has been best documented.<sup>70</sup> Pulmonary sporotrichosis typically presents in the fifth decade of life with productive cough and upper lobe chest radiographic findings.<sup>64</sup> Most commonly, chest radiography reveals a solitary upper lobe thin-walled cavity with surrounding parenchymal infiltrate. Untreated pulmonary sporotrichosis is usually associated with progressive disease and death. Osteoarticular sporotrichosis is an indolent disease usually involving the joints of the knee, elbow, wrist, or ankle.<sup>71,72</sup> Infection presents like osteoarthritis or rheumatoid arthritis with gradual onset of pain, stiffness, and decrease in range of motion. Localized swelling is often present. Laboratory studies usually show an elevated erythrocyte sedimentation rate and synovial fluid with decreased glucose, increased protein, and leukocytes. Hematogenous spread from the lungs or occult sites may lead to chronic meningitis, endophthalmitis, brain abscesses, or disseminated skin lesions.

## PATHOGENESIS AND IMMUNITY

The virulence factors and pathogen-host immunity interaction of *S. schenckii* are not currently well understood. *S. schenckii* has limited pathogenicity in laboratory animals, with large inocula being required to establish infection. Virulence of strains of *S. schenckii* can be subdivided by thermotolerance as those strains which grow at 37°C are better able to cause disseminated disease. Antibody to yeast cell wall antigens is produced in some infections. The role of this antibody in

containing infection is not believed to be critical, although agglutinating antibody response in a hamster model has been associated with protection against challenge.<sup>73</sup> Cell-mediated immunity (CMI) likely serves a more important role in host defense, especially in humans. Human neutrophils have been shown to phagocytose and kill *S. schenckii*. This killing requires halide, myeloperoxidase, and peroxide.<sup>74</sup> Opsonization with human serum is thought to enhance this interaction via activation of the alternative complement pathway. Athymic mice have been shown to be unable to clear an intravenous challenge of *S. schenckii* when compared with euthymic mice,<sup>75</sup> further supporting the role of CMI.

## DIAGNOSIS

Diagnosis of cutaneous sporotrichosis is suspected with observation of typical lesions, often with supporting history of likely exposure (e.g., agriculture, gardening, or forestry). This diagnosis is then confirmed by culture or further supported by microscopic tissue examination. The differential diagnosis of cutaneous sporotrichosis includes disease caused by *Nocardia* species (especially *N. brasiliensis*), *Mycobacterium* species (*M. marinum*, *M. chelonae*, *M. fortuitum*, and *M. kansasii*), leishmaniasis, tularemia, cat-scratch disease, chromoblastomycosis, blastomycosis, and paracoccidioidomycosis. An incorrect diagnosis of squamous cell carcinoma may be made from biopsy specimens that manifest hyperkeratosis and are not cultured correctly. Pulmonary sporotrichosis should be differentiated from *Mycobacterium avium-intracellulare* (MAI) complex infection, coccidioidomycosis, tuberculosis, and histoplasmosis. In addition to chronic bacterial osteomyelitis, osteoarticular sporotrichosis should be differentiated from mycobacterial infections. Diagnosis of pulmonary disease is usually made when *S. schenckii* is cultured from sputum, bronchoalveolar lavage, or biopsy. Osteoarticular disease may be diagnosed by culture of joint fluid or fungal stain of synovium. Blood culture is not usually helpful in the diagnosis of sporotrichosis. Although both localized<sup>76</sup> and disseminated<sup>77</sup> disease has been diagnosed by blood culture, these represent only a handful of cases. *S. schenckii* is best recovered on brain-heart infusion agar incubated at 25°C to 30°C for up to 3 weeks. Histopathologic study reveals a pyogranulomatous reaction with neutrophils and necrotic debris surrounded by epithelioid cells. In more chronic lesions, pseudoepitheliomatous hyperplasia is seen. Commonly, skin lesions have a paucity of fungal organisms, making the correct diagnosis difficult to establish without culture. It is often very difficult to find *S. schenckii* in routine H&E-stained histopathologic sections in any tissue. PAS and GMS stains improve visualization of the organism in tissue. Usually seen as oval- to cigar-shaped yeasts in tissue, *S. schenckii* may also form asteroid bodies or appear as spherical yeasts with what appears to be a capsule. The asteroid body is a central rounded yeast structure with radiating eosinophilic substance in tissue. Deposition of eosinophilic material about the infecting organism was first described by Splendore in 1908 in the study of sporotrichosis,<sup>78</sup> and then in 1932 by Hoeppli in the study of schistosomiasis in a rabbit model.<sup>79</sup> Classically, the Splendore-Hoeppli phenomenon is believed to be an immune complex (antibody-antigen) deposition. Study employing electron microscopy appears to indicate that the asteroid bodies of sporotrichosis may actually be

comprised of disintegrated immune cells.<sup>80</sup> This phenomenon has also been seen in schistosomiasis, actinomycosis, botryomycosis, entomophthoromycosis, mycetoma, and onchocerciasis. In its atypical spherical form with a PAS-positive capsular-appearing structure, *S. schenckii* may be confused with *Cryptococcus neoformans*. Serologic and immune testing is generally of limited value in the diagnosis of sporotrichosis. Although many testing formats have been developed, the availability of these tests and perceived need for them has limited their usefulness.

## TREATMENT

The treatment of sporotrichosis is based on the clinical presentation of the disease.<sup>81</sup> Treatment of all forms of this disease has been associated with relapse. Potassium iodide in saturated solution has been the mainstay of therapy of cutaneous sporotrichosis since the beginning of this century. First used by Beurmann for the treatment of cutaneous disease, potassium iodide remains an inexpensive, effective therapy. Iodide therapy can be poorly tolerated and associated with adverse effects. It is a bitter solution, which should be slowly titrated up to treatment doses to minimize adverse effects and increase tolerance.<sup>82</sup> These effects include excessive tearing and salivating, parotid enlargement, acne, and gastrointestinal upset. Supersaturated solution of potassium iodide (~1 g/mL or 47 mg/drop) can be begun at a dose of 5–10 drops three times daily, usually with juice or water. The dose can be increased slowly (5 drops per dose each week) to 25–40 drops thrice daily in those under 10 years of age and 40–50 drops thrice daily in those 10 years old or older. The duration of therapy is usually 6 to 12 weeks (until lesions are flat and soft). Itraconazole is an effective, well-tolerated alternative to iodide in the therapy of cutaneous disease. Its biggest limitation in many areas of the world is its cost. In those patients with plaque sporotrichosis who cannot tolerate iodide, heat may be beneficial. Hyperthermic therapy using a variety of modalities has been used successfully in these cutaneous infections. Successes with therapies using liquid nitrogen,<sup>83</sup> fluconazole,<sup>84</sup> saperconazole,<sup>85</sup> and terbinafine<sup>86</sup> have also been reported in cutaneous disease. Interestingly, the new broad spectrum azole voriconazole was shown in one study to be less active than itraconazole against *S. schenckii*.<sup>87</sup> Both itraconazole and amphotericin B have been shown to be effective in osteoarticular disease.<sup>88,89</sup> Intra-articular injection with amphotericin B has been reported to lead to improvement in several patients with disease recurring after parenteral therapy.<sup>72,90</sup> Doses ranging from 0.1 mg to 10 mg of amphotericin B injected daily to every 2 weeks have been used. Pulmonary sporotrichosis has been treated with amphotericin B, iodide, ketoconazole, miconazole, and itraconazole, all with some reported successes. Unfortunately, pulmonary disease does not respond regularly to antifungal therapy and is known to relapse. This disease is best treated surgically with or without the addition of amphotericin B or itraconazole. Disseminated sporotrichosis is most often treated with parenteral amphotericin B. Itraconazole therapy has been shown in several reports to lead to a favorable response, usually in those patients not responding to amphotericin B.<sup>88,91</sup>

## PREVENTION

Prevention of sporotrichosis is based on avoidance of traumatic inoculation of the fungus. Fungicide treatment

of timbers was used to bring a halt to the epidemic of disease seen in South African gold mines in the 1940s. The U.S. outbreak involving conifer saplings packed in sphagnum moss has led to suggestions of using chipped wood or shredded paper as packing material for these plants.<sup>92</sup> People who work in forestry or horticulture and others who are engaged in gardening should be encouraged to wear gloves and clothing that cover their extremities, preventing scratches and other minor trauma. Similar recommendations can be made for veterinarians and others handling pets with skin lesions.

# Pneumocystosis

PETER D. WALZER

## INTRODUCTION

*Pneumocystis* was discovered by Chagas in 1909 during his studies of American trypanosomiasis. The organism was established as a separate genus and species a few years later by the Delanões, who named it in honor of Dr. Carini. *Pneumocystis* is an organism of low virulence that resides in the lungs of humans and many animals in nature.

## AGENTS

Although *Pneumocystis* isolates from these hosts are morphologically indistinguishable, molecular, antigenic, and experimental transmission studies have demonstrated a high degree of genetic diversity and host specificity. This information has resulted in new nomenclature that has established the following *Pneumocystis* species: *P. carinii* and *P. wakefieldii* in rats, *P. murina* in mice, and *P. jirovecii* in humans.<sup>1-3</sup> *Pneumocystis* was first recognized as the pathogen that caused interstitial plasma cell pneumonia in premature, malnourished infants in European orphanages following World War II. However, the disease can occur wherever these conditions exist. More recently, *Pneumocystis* has been found to be a leading cause of pneumonia in immunocompromised patients, such as those infected with the human immunodeficiency virus (HIV).

Knowledge of the basic biology of *Pneumocystis* has been limited by the lack of a continuous in vitro culture system.<sup>4</sup> The developmental stages that have been identified include the 5- to 8- $\mu$ m cyst or spore case, which has a thick wall and contains up to eight intracystic bodies or spores; the 1- to 4- $\mu$ m trophozoite or trophic form, which is the most numerous stage; and the precyst or sporocyte, an intermediate stage. A proposed life cycle is presented in Figure 85-1.<sup>5</sup> The cyst (spore case) is thought to develop through a sexual cycle that culminates in the release of the intracystic bodies (spores), which then become trophic forms; the trophic forms replicate asexually by binary fission. The taxonomic status of *Pneumocystis* has clearly established the organism as a member of the fungi.<sup>4</sup>

## EPIDEMIOLOGY

Serologic studies have revealed that *Pneumocystis* has a worldwide distribution, and that exposure to the organism occurs early in life.<sup>6,7</sup> Evidence suggests that *Pneumocystis* remains in the lungs for limited periods of time and that people may be transiently infected at different times in their lives.

The HIV pandemic changed pneumocystosis from a sporadic disease to a problem of major medical and public health importance. Although the incidence of *Pneumocystis* pneumonia has fallen with widespread chemoprophylaxis and antiretroviral therapy, the organism remains the leading cause of opportunistic infection in HIV patients in industrialized countries.<sup>8</sup> Evaluation of the evidence of pneumocystosis in tropical and developing countries has been hampered by lack of access to medical care and the higher frequency of more virulent infection such as tuberculosis.<sup>9</sup> These factors have led to an underestimate of the true frequency of this disease. Recently, a high frequency of *Pneumocystis* has been reported in pediatric HIV patients in developing countries.<sup>10</sup> Other factors affecting the epidemiology are geography and season of the year.<sup>11,12</sup>

Studies in animal models have demonstrated that *Pneumocystis* is communicable via the airborne route.<sup>5</sup> Young animals acquire *Pneumocystis* infection soon after birth and play an important role in spreading the infection.<sup>13</sup> Molecular studies in humans support the findings from these experimental models.<sup>14</sup> The incubation period is approximately 4 to 8 weeks.

## DISEASE

Risk factors for pneumocystosis include prematurity and malnutrition; primary immunodeficiency disorders, particularly severe combined immunodeficiency disease; infection with HIV; and cytotoxic or immunosuppressive drugs for the treatment of cancer, transplantation, and collagen vascular disorders. Studies of HIV-infected and AIDS patients have documented a significant risk of pneumocystosis when CD4 lymphocyte counts fall below 200/ $\mu$ L; other risk factors include persistent constitutional symptoms.<sup>15,16</sup> Corticosteroids are by far the most commonly used immunosuppressive drugs that predispose to *Pneumocystis* pneumonia in non-HIV-infected patients.<sup>17</sup> Symptoms often begin after the steroid dose has been tapered.

*Pneumocystis* pneumonia is characterized by the triad of dyspnea, nonproductive cough, and fever.<sup>18</sup> Although a productive cough and chest tightness may occur, purulent sputum should raise suspicion of bacterial infection. HIV-infected patients frequently have prolonged prodromal periods with subtle clinical manifestations; other immunocompromised hosts are usually ill for 1 or 2 weeks before they seek medical attention.<sup>19</sup> However, the clinical picture varies in individual patients. Physical examination reveals varying degrees of respiratory distress. Lung auscultation is nonrevealing, although basilar rales may occasionally be present. On the chest radiograph, typically these are diffuse infiltrates with symmetric reticular or granular opacities emanating from the perihilar regions (Fig. 85-2).<sup>20</sup> Unusual manifestations include focal infiltrates, lobar consolidation, nodules, cavities, effusions, pneumatoceles, and lymphadenopathy.<sup>21</sup> An increased frequency of pneumothorax and apical infiltrates has been noted with the administration of aerosolized pentamidine.<sup>22</sup> Very early in *Pneumocystis* pneumonia, the chest radiograph may be normal.

The principal laboratory abnormality is arterial hypoxemia with an increased alveolar-arterial (PAO<sub>2</sub>-PaO<sub>2</sub>) gradient; this is often accompanied by respiratory alkalosis.<sup>23</sup>

**FIGURE 85-1** Proposed life cycle of *Pneumocystis carinii*. Photographs depict living trophic and cyst forms by Nomarski interference contrast microscopy. In the asexual phase, the trophic forms replicate by mitosis and cell division. In the sexual phase, the haploid trophic forms (mating types) conjugate to form a diploid zygote (early phase) that undergoes meiosis and subsequent mitosis to form eight haploid nuclei (late phase). The spores are formed by compartmentalization of nuclei and cytoplasmic organelles (e.g., mitochondria). The spores exhibit different shapes, including spherical and elongated forms. It is postulated that the elongation of the spores precedes release from the ascus. Release is thought to occur through a rent in the cell wall. After evacuation, the empty ascus usually collapses but retains some residual cytoplasm. (From Cushion M: *Pneumocystis carinii*. In Collier L, Balows A, Sussman M [eds]: Topley and Wilson's Microbiology and Microbial Infections, Vol. 4. New York, Oxford University Press, 1998, pp 645–683.)

**FIGURE 85-2** Chest radiograph from an HIV-infected patient with pneumocystosis. Note the typical bilateral infiltrates. (From Walzer PD, Kim CK, Cushion MT: *Pneumocystis carinii*. In Walzer PD, Genta RM [eds]: Parasitic Infections in the Compromised Host. New York, Marcel Dekker, 1989, pp 83–178.)

Blood oxygenation may be normal early in the course of pneumocystosis but will desaturate with exercise. Pulmonary function tests are characterized by alterations in lung volumes and spirometry (e.g., reversible airway obstruction and airway hyperreactivity). The diffusing capacity for carbon monoxide ( $DL_{CO}$ ) has been sensitive in detecting alveolar–capillary block. Serum lactic dehydrogenase (LDH) levels, which reflect the degree of lung injury, increase with progression of pneumocystosis and decrease as the disease is treated. Imaging techniques such as the chest high-resolution computed tomograph (HRCT) may show abnormal findings (especially ground-glass opacities) but are not specific for *Pneumocystis*.<sup>24</sup>

The spread of *Pneumocystis* beyond the lungs is well recognized. The frequency of extrapulmonary pneumocystosis is unknown, although estimates range from uncommon to as high as 3% of cases.<sup>25,26</sup> Patients at highest risk are those in the late stages of HIV infection who have received aerosolized pentamidine or have not taken prophylaxis. The most common sites of extrapulmonary infection are the lymph nodes, spleen, liver, and bone marrow, although most organs in the body have been involved. Clinical features range from incidental findings at autopsy to focal involvement and systemic disease.

The natural history of untreated *Pneumocystis* pneumonia in HIV-infected and other immunocompromised patients is

**FIGURE 85-3** Lungs displaying the characteristic foamy, vacuolated alveolar exudates (H&E; ×300). (Courtesy of Dr. Paul Steele, Cincinnati, OH.)

one of progressive respiratory impairment ending in death.<sup>8,27</sup> Since recovery from pneumocystosis does not confer immunity, patients are at risk of recurrence as long as the predisposing conditions exist; HIV-infected patients are at highest risk for this complication. Other problems that can complicate recovery include bullous lesions, cavities, and pneumothorax that appear to result from the tissue destruction and inflammation that accompany the infection. Similarly, chronic airway disease can develop, which may be complicated by bacterial infections.

Histopathologically, *Pneumocystis* pneumonia is characterized by the presence of a foamy, vacuolated exudate filling alveoli in lung sections stained with hematoxylin and eosin (Fig. 85-3). The use of stains such as methenamine silver reveals masses of *Pneumocystis* cysts (Fig. 85-4).<sup>20</sup> With severe disease, there may be interstitial fibrosis, edema, and the development of hyaline membranes. Hypertrophy of type II alveolar cells, which suggests tissue repair, is often present; however, other aspects of the host inflammatory response in HIV-infected and other immunocompromised patients are

**FIGURE 85-4** Lungs demonstrating clusters of *Pneumocystis carinii* cysts in the alveolar exudate (Methenamine silver stain; ×900). (From Walzer PD, Kim CK, Cushion MT: *Pneumocystis carinii*. In Walzer PD, Genta RM [eds]: *Parasitic Infections in the Compromised Host*. New York, Marcel Dekker, 1989, pp 83–178.)

mild and nonspecific. In contrast, premature or malnourished infants display an interstitial plasma cell infiltrate, which was responsible for the name of interstitial plasma cell pneumonia. Extrapulmonary lesions of pneumocystosis display the typical foamy material found in the lungs.

## **PATHOGENESIS AND IMMUNITY**

The mechanisms by which *Pneumocystis* causes disease are poorly understood. Although several different enzymes have been identified, evidence that these enzymes are virulence factors is lacking. Several groups of antigens have been identified, of which the major surface glycoprotein (Msg or gpA) has received the most attention.<sup>28</sup> Msg is actually a family of proteins encoded by multiple genes and is thus capable of antigenic variation; this variation may help *Pneumocystis* to evade host defenses.<sup>29</sup> Msg is highly immunogenic, contains protective epitopes, and plays a major role in the interaction of the organism with host cells.<sup>30–33</sup> Studies have shown that HIV patients who recovered from pneumocystosis have significantly higher serum antibodies to recombinant Msg than HIV patients who never had *Pneumocystis* pneumonia.<sup>34,35</sup>

Pneumocystosis develops when there are impairments in cellular or humoral immunity.<sup>28</sup> Predisposing T cell defects can result from the underlying disease (HIV infection) or immunosuppression (corticosteroids). The central role of CD4 cells in host defenses against *Pneumocystis* has been shown by cell depletion and reconstitution experiments.<sup>32,36,37</sup> CD8 cells and  $\gamma\delta$  T cells also participate in host defenses against *Pneumocystis*, but their specific roles have not been well delineated.<sup>38,39</sup> The development of *Pneumocystis* pneumonia is also favored by the disruption of the interaction of T cells with B cells or other effector cells.<sup>40</sup> The importance of humoral immunity is evidenced by the occurrence of pneumocystosis in patients or animals with B cell defects, the beneficial effect of passive immunotherapy, and active immunization.<sup>30,41–44</sup> Antibodies do not have a direct lethal effect on *Pneumocystis* but probably function as opsonins.

After being inhaled, *Pneumocystis* eludes the upper airway defenses and lands in alveoli, where it takes up residence. Alveolar macrophages constitute the first line of defense and are the principal host effector cell against *Pneumocystis*.<sup>45</sup> Recognition and adherence of the organism occur by multiple pathways involving the interaction of Msg with extracellular matrix proteins (fibronectin, vitronectin, and laminin), surfactant proteins A (SP-A) and D (SP-D), and the mannose and Fc receptors.<sup>46–49</sup> HIV downregulates the mannose receptor, which leads to reduced binding and uptake of *Pneumocystis*.<sup>50</sup> Interaction with macrophages stimulates an oxidative burst and cytokine production. Once the organism is engulfed by the macrophage, it is rapidly killed.<sup>51</sup> Of the cytokines produced in response to *Pneumocystis*, tumor necrosis factor- $\alpha$ , interleukin-1 (IL-1), interferon- $\gamma$ , and granulocyte-macrophage colony-stimulating factor have been shown to have a role in host defenses against the infection.<sup>52–55</sup>

Within the alveolus, *Pneumocystis* adheres tightly to the alveolar type I cell, which plays an important role in the host–parasite relationship in this infection.<sup>56</sup> This process requires an intact cytoskeleton and results in enhanced proliferation of the organism and suppression of lung cell growth.<sup>57</sup> *Pneumocystis* is held in check within the lung as long

as the host defenses remain intact. However, once these defenses break down, the organism begins to propagate slowly and fill the alveolar lumen. Accompanying changes include disruption of the alveolar–capillary membrane, impaired gas exchange, and ventilation–perfusion abnormalities similar to the changes seen in adult respiratory distress syndrome.<sup>27</sup> There is increasing evidence that changes in the surfactant system and host inflammatory response contribute to these lung abnormalities. There is a decline in surfactant phospholipids SP-B and SP-C, with a concomitant increase in SP-A and SP-D levels.<sup>58–61</sup> Animal studies have demonstrated a hyperinflammatory response with elevation of multiple cytokines.<sup>32,62–65</sup> In some models, CD4 cells play a contributing role, whereas in other models CD8 cells are responsible. In humans with pneumocystosis, elevated levels of IL-8 and neutrophils in bronchoalveolar lavage fluid (BALF) have been associated with more severe disease and worse prognosis.<sup>66,67</sup> HIV patients experience a clinical deterioration soon after beginning treatment for *Pneumocystis* pneumonia. This problem can be ameliorated by the administration of corticosteroids, but the mechanism of action of these drugs is unclear.<sup>68</sup>

## DIAGNOSIS

The clinical manifestations of pneumocystosis can be mimicked by a wide variety of infectious and noninfectious agents. Optimal management requires that a specific diagnosis be made by identification of the organism in properly obtained specimens. *Pneumocystis* is rarely present in expectorated sputum. However, induced sputum, obtained by breathing in a saline mist, has gained popularity as a simple and inexpensive screening technique.<sup>69</sup> Induced sputum is best obtained by specially trained personnel; its sensitivity varies widely among different health care facilities and patient populations.

Fiber-optic bronchoscopy with BAL remains the mainstay of *Pneumocystis* diagnosis, with a yield equal to or greater than 90% and a low rate of complications.<sup>23,70</sup> The efficacy of BAL can be increased if multiple lobes are sampled or if the procedure is directed toward the site of greatest involvement.<sup>71</sup> BAL also provides information not obtainable from induced sputum about the *Pneumocystis* burden, the presence of other opportunistic infections, and the host inflammatory response.<sup>72</sup> Bronchoscopy with transbronchial biopsy can sometimes provide information not obtainable with BAL, but it is more invasive and has a higher rate of complications.<sup>71</sup> Open lung biopsy, the most invasive procedure, is usually reserved for situations in which a diagnosis cannot be made by bronchoscopy.<sup>23,70</sup> One condition particularly amenable to open biopsy is Kaposi's sarcoma of the lungs.

Several types of histologic stains have been used to identify *Pneumocystis*. Those that selectively stain the wall of the cyst stage of the organism (e.g., methenamine silver, toluidine blue O, and cresyl violet) are popular because they are versatile and easy to interpret (see Fig. 85-4).<sup>20,73</sup> Stains that demonstrate the nuclei of all *Pneumocystis* developmental stages (e.g., Wright–Giemsa and Diff-Quik) can provide a diagnosis within minutes but require some expertise in interpretation (Fig. 85-5). Other reagents, such as the Papanicolaou stain and calcofluor white, a chemiluminescent agent, have been popular in some laboratories. Immunofluorescent staining with monoclonal antibodies is more sensitive than histologic

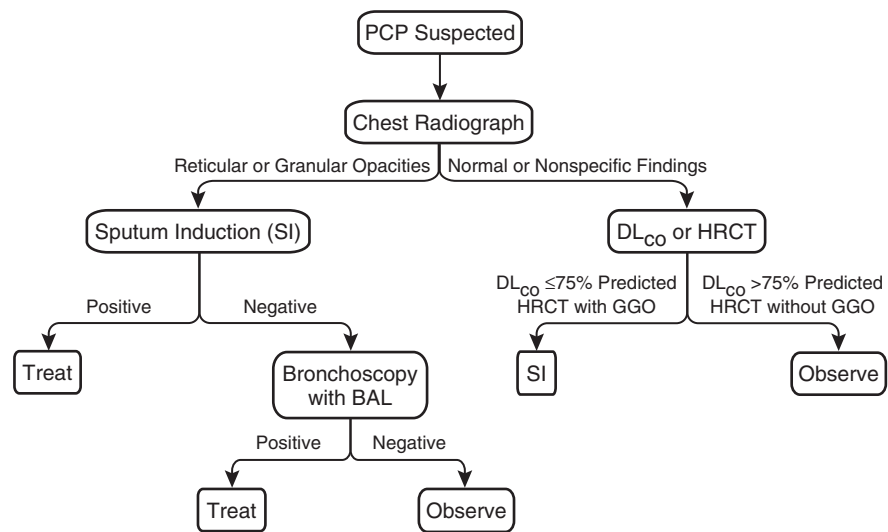

**FIGURE 85-5** Clusters of *Pneumocystis carinii* trophic forms and cysts with intracystic bodies (Diff-Quik stain;  $\times 1700$ ). (From Walzer PD, Kim CK, Cushion MT: *Pneumocystis carinii*. In Walzer PD, Genta RM [eds]: *Parasitic Infections in the Compromised Host*. New York, Marcel Dekker, 1989, pp 83–178.)

stains, but it is more expensive and requires specialized facilities.<sup>73,74</sup> Soluble *Pneumocystis* antigens have been found in BALF by immunoblotting, but this technique is investigational.<sup>75</sup> DNA amplification by the polymerase chain reaction (PCR) is the most sensitive method of detecting *Pneumocystis*.<sup>76–79</sup> Although PCR is not licensed, it has been adapted for use by noninvasive sampling techniques (e.g., oropharyngeal washes) and for analysis by clinical laboratories.<sup>77</sup> The clinical significance of a positive PCR product in the absence of other confirmatory tests or respiratory illness is unclear. Reverse transcription PCR can distinguish RNA of viable organisms from DNA.<sup>78</sup>

Definitive diagnosis of pneumocystosis is best made using a coordinated approach that involves several different clinical services. Some institutions, such as the San Francisco General Hospital, where *Pneumocystis* pneumonia is frequently encountered, have developed algorithms that have been highly successful (Fig. 85-6).<sup>69,78</sup> Patients with clinical and x-ray manifestations compatible with pneumocystosis first undergo sputum induction. If this measure reveals the organism, treatment is begun. If induced sputum is nondiagnostic, BAL is performed. If the BAL reveals *Pneumocystis*, treatment is begun. A negative BAL is followed by observation. Patients with a normal chest radiograph undergo either HRCT or DL<sub>CO</sub>. An HRCT with ground-glass opacities or DL<sub>CO</sub> less than 75% suggest the presence of *Pneumocystis*; the patients then undergo sputum induction. If the HRCT or DL<sub>CO</sub> does not suggest the presence of *Pneumocystis*, the patients are observed.

Another approach has been to use empirical therapy. Although empirical therapy may be routinely practiced in areas of the world with few diagnostic facilities, this approach has been controversial in industrialized countries. Situations in which empirical therapy may be considered include a reliable patient with a CD4 cell count of less than 200/ $\mu$ L who can take oral drugs, mild disease with typical radiologic

**FIGURE 85-6** Diagnostic algorithm for the evaluation of patients with suspected PCP used at San Francisco General Hospital. BAL, bronchoalveolar lavage;  $DL_{CO}$ , single-breath diffusing capacity for carbon monoxide; GGO, ground-glass opacities; HRCT, high-resolution computed tomograph. (Redrawn from Huang L: Clinical presentation and diagnosis of PCP in HIV-infected patients. In Walzer PD, Cushion MT [eds]: *Pneumocystis Pneumonia*. New York, Marcel Dekker, 2004.)

features, no previous anti-*Pneumocystis* prophylaxis, and a low probability of other diseases (e.g., tuberculosis).<sup>80</sup> Such patients should be followed closely and hospitalized for definitive diagnostic evaluation if they fail to respond to therapy.

## TREATMENT AND PROGNOSIS

The outlook for HIV-infected patients who develop pneumocystosis has improved during the past decade with earlier detection of the disease, prompt institution of therapy, and better management of complications. Several large series of patients hospitalized with *Pneumocystis* pneumonia had mortality rates of 15% to 20% at 1 month and 50% to 55% at 1 year after diagnosis.<sup>81</sup> Among patients who have taken *Pneumocystis* prophylaxis or have milder forms of the disease, mortality is less than 10%.<sup>82</sup> The most widely used prognostic indicator has been the degree of hypoxemia (arterial oxygen pressure,  $PaO_2$ ), which has been used to stratify patients for treatment trials (Fig. 85-7).<sup>68</sup> This laboratory test has been expressed in the following way when breathing room air: A  $PaO_2$  greater than 70 mmHg indicates mild disease, and a value of less than 70 mmHg indicates moderate to severe disease. Similarly, the  $PAO_2$ – $PaO_2$  on room air has been categorized as mild (<35 mmHg), moderate (35–45 mmHg), or severe (>45 mmHg). Other prognostic factors include broad markers of disease severity, such as the APACHE (Acute Physiology and Chronic Health Evaluation) score, serum LDH, extent of abnormalities on chest radiography, the presence of fibrosis and edema on biopsy, levels of IL-8 and neutrophils, and possible cytomegalovirus in BAL fluid.<sup>23,27</sup>

The drug of choice for all forms of pneumocystosis is trimethoprim (TMP)–sulfamethoxazole (SMX).<sup>8</sup> This drug combination, which has been used for two decades, works by inhibiting the synthesis of folic acid. The drug is given orally or intravenously in a dose of 15 to 20 mg/kg/day TMP and 75 to 100 mg/kg/day SMX in three or four divided doses for 21 days. The parenteral preparation is indicated for patients who have difficulty taking oral medications or who are seriously ill. The major limitation of TMP–SMX is the high frequency (up to 80% or higher) of side effects that necessitate discontinuation of the drug in up to half of HIV-infected patients.<sup>8,83</sup>

These adverse reactions, which usually begin during the second week of treatment, consist of rash, fever, neutropenia and other cytopenias, nausea and vomiting, hepatitis, hyperkalemia, pancreatitis, nephritis, and central nervous system manifestations. The mechanisms of TMP–SMX toxicity are incompletely understood but may be related to elevated serum concentrations of the drug, the formation of toxic intermediate (hydroxylamine) metabolites, glutathione deficiency, hypersensitivity, the CD4 count, and its action as a potassium-sparing diuretic.<sup>83</sup>

Several strategies have been devised to minimize these adverse reactions. One approach has been to adjust the dose

**FIGURE 85-7** Risk of death according to the partial pressure of oxygen in room air at admission of 278 HIV-infected patients with pneumocystosis at the San Francisco General Hospital. Box plots represent the 25th percentile, the median, and the 75th percentile with survivors and nonsurvivors, with bars extending to the 5th and 95th percentiles. (From The National Institutes of Health–University of California Expert Panel for Corticosteroids as Adjunctive Therapy for *Pneumocystis carinii* Pneumonia: Consensus statement on the use of corticosteroids as adjunctive therapy for *Pneumocystis pneumonia* in the acquired immunodeficiency syndrome. *N Engl J Med* 323:1500–1504, 1990.)

of the drug to achieve serum concentrations of 5 to 8  $\mu\text{g/mL}$  TMP and 100 to 150  $\mu\text{g/mL}$  SMX in serum.<sup>83</sup> However, other investigators have not found this to be helpful.<sup>84</sup> The use of folinic acid (leucovorin) has not been helpful in preventing myelosuppression,<sup>85</sup> and appeared to exacerbate pneumocystosis in one study.<sup>86</sup> In some patients, mild side effects, such as fever or skin rash, may disappear spontaneously or respond to conservative measures. However, in other cases these adverse effects progress to the point where they require discontinuation of the drug. Desensitization protocols have been effective in patients who have suffered non-life-threatening reactions to TMP-SMX, but caution is advised.<sup>87</sup> Corticosteroids may also be helpful.<sup>88</sup>

Several alternative oral regimens are available for the treatment of mild to moderate cases of *Pneumocystis pneumonia*.<sup>89</sup> TMP 15 mg/kg/day in three divided doses combined with dapsone 100 mg/day was shown in one trial to be equally as effective as TMP-SMX but less toxic.<sup>90</sup> Many patients intolerant of TMP-SMX can safely take TMP plus dapsone. However, caution is advised in using this combination because it is difficult to predict who might experience an adverse reaction. Side effects of TMP and dapsone include hemolysis [especially in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency], methemoglobinemia, neutropenia, nausea, vomiting, fever, and skin rash.<sup>83</sup> The administration of TMP plus dapsone produces bidirectional drug interactions with higher serum levels of both drugs.<sup>91</sup> Didanosine, the anti-HIV drug, interferes with the absorption of dapsone. Another regimen that has shown promising activity against *Pneumocystis* in several trials is clindamycin plus primaquine base (15–30 mg/day).<sup>92,93</sup> Typically, the oral dose of clindamycin is 300 to 450 mg four times a day. The mechanisms of action of these drugs are unknown. Principal side effects include rash, methemoglobinemia, hemolysis (G6PD deficiency), gastrointestinal disturbances, and transient neutropenia. A large, double-blind, randomized trial compared TMP-SMX, TMP plus dapsone, and clindamycin plus primaquine for therapy of mild to moderate pneumocystosis.<sup>82</sup> Similar rates of dose-limiting toxicity, therapeutic failure, and survival were observed among the three regimens, although there were differences in the types of adverse reactions encountered.

Other regimens that have been studied are atovaquone and aerosolized pentamidine isethionate. Atovaquone is a hydroxynaphthoquinone that acts against plasmodia by inhibiting mitochondrial electron transport. Analysis of mutations in *Pneumocystis* isolates in patients who failed atovaquone suggests a similar site of action. In comparative studies, atovaquone was less effective but better tolerated than TMP-SMX or parenteral pentamidine.<sup>94,95</sup> The major side effects of atovaquone were fever, rash, gastrointestinal disturbances, and abnormal liver function tests. Atovaquone is a highly lipophilic compound with poor bioavailability. An oral suspension of atovaquone, administered at a dose of 750 mg/5 mL twice a day with food, is better absorbed than previous tablet preparations.<sup>96</sup> Pentamidine is a diamidine that has been used to treat African trypanosomiasis and pneumocystosis for several decades. Its mechanism of action against *Pneumocystis* is unknown. Pentamidine is ordinarily administered parenterally and is highly toxic. The administration of pentamidine via aerosol is attractive because it should produce high concentrations of the drug in the lungs.

Although aerosolized pentamidine has been used in the therapy of pneumocystosis, it is not as effective as the oral drugs and thus cannot be recommended.<sup>97</sup> The main clinical use of aerosolized pentamidine is for prophylaxis.

Pentamidine is the principal drug used to treat patients intolerant of TMP-SMX who have moderate to severe pneumocystosis, are acutely ill, or require parenteral drugs. Pentamidine is administered at a dose of 4 mg/kg/day intravenously over at least 1 hour to minimize the risk of hypotension.<sup>8,89</sup> After injection, pentamidine pharmacokinetics follow a three-compartment model with rapid distribution to tissues, secondary distribution, and a long elimination half-life.<sup>83,98</sup> Only a small fraction of pentamidine is excreted in the urine. Autopsy studies have suggested that it takes at least 5 days for pentamidine to reach therapeutic concentrations in the lung.<sup>99</sup> Adverse reactions to pentamidine occur in more than 80% of patients and require discontinuation of the drug in approximately half the cases.<sup>100–102</sup> The principal side effects are azotemia, cardiac arrhythmias (e.g., torsades de pointes), neutropenia, hypoglycemia, pancreatitis, hypocalcaemia, hypomagnesemia, and hepatic abnormalities. Hypoglycemia is due to insulin release with pancreatic islet damage. It typically occurs early and may be followed by diabetes mellitus. The frequency of hypoglycemia and azotemia increases with pentamidine serum levels greater than 100 ng/mL, total drug dose, and duration of therapy.<sup>103,104</sup> Hyperkalemia due to pentamidine toxicity as a potassium-sparing diuretic has also been reported.<sup>105</sup> A dose of 3 mg/kg/day appears to be better tolerated, but controlled studies are lacking.

Alternatives for patients with moderate to severe *Pneumocystis pneumonia* who fail or cannot tolerate treatment with TMP-SMX or pentamidine include trimetrexate and the combination of clindamycin plus primaquine.<sup>8,89</sup> Trimetrexate is a lipophilic analogue of methotrexate that acts by inhibiting *Pneumocystis* dihydrofolate reductase. The adult dose of trimetrexate is 45 mg/m<sup>2</sup>/day intravenously. Folinic acid is administered at a dose of 20 mg/m<sup>2</sup> orally or intravenously every 6 hours to protect against bone marrow depression, the principal adverse effect of trimetrexate. Other side effects are skin rash and liver function abnormalities. In one controlled trial, trimetrexate was less effective but better tolerated than TMP-SMX in patients with pneumocystosis serious enough to require hospitalization and parenteral drugs.<sup>106</sup> However, the real benefit of trimetrexate may be as “salvage” therapy for *Pneumocystis pneumonia* patients who have limited treatment options.

Clindamycin 600 to 900 mg every 6 to 8 hours intravenously plus primaquine base 15 to 30 mg/day orally have been used successfully in patients with moderate to severe pneumocystosis.<sup>92,107</sup> Because of limited clinical experience and because primaquine is only available as an oral preparation, this combination should be used with caution in patients who are acutely ill.

During the first few days of treatment, HIV patients with *Pneumocystis pneumonia* frequently experience a worsening of their respiratory status. In patients with marginal blood oxygenation, this deterioration may require intubation. The underlying mechanism is thought to be the host inflammatory response to products released from dying *Pneumocystis* organisms and/or surfactant changes that exacerbate lung injury. Several studies have shown that corticosteroids administered

within the first 72 hours of treatment can prevent this deterioration and improve survival; however, administration of steroids after 72 hours was of no benefit. These data led a National Institutes of Health expert panel to recommend corticosteroids for all patients with moderate to severe pneumocystosis ( $\text{PAO}_2 < 70$  mmHg,  $\text{PAO}_2 - \text{PaO}_2 > 35$  mmHg) according to the following oral regimen: prednisone 40 mg twice daily on days 1 to 5; 40 mg once daily on days 6 to 10; and 20 mg once daily on days 11 to 21.<sup>68</sup> Although a later study questioned whether the steroids improved the rate of recovery,<sup>108</sup> a meta-analysis supported the value of these drugs.<sup>109</sup> The adverse effects of the corticosteroids have been limited primarily to metabolic alterations such as hyperglycemia and exacerbation of infections such as thrush and mucocutaneous herpes simplex; nevertheless, concerns about other complications (e.g., pneumothorax) emphasize the need for judicious use of these drugs and careful patient follow-up.<sup>27,110,111</sup> Further investigation is needed to determine whether steroids are beneficial in patients with mild pneumocystosis and in pediatric patients.

In contrast to HIV-infected patients, the prognosis of pneumocystosis in other immunocompromised hosts has not changed appreciably during the past two decades. Although there have been few prospective studies, retrospective surveys of non-HIV-infected patients treated at tertiary care facilities have revealed mortality rates of 30% to 50%.<sup>17,112,113</sup> All non-HIV-infected patients suspected of having *Pneumocystis* pneumonia should be admitted to the hospital for definitive diagnosis because the disease progresses more rapidly in these people than in patients with HIV infection. TMP-SMX administered for 14 days is the treatment of choice and is well-tolerated by non-HIV-infected patients; the principal side effects are gastrointestinal disturbances and skin rash. The choice of alternative drugs is probably best guided by the severity of the pneumocystosis and the clinical status of the patient. Pentamidine, the other major drug used in non-HIV-infected patients, is about as effective as TMP-SMX but much more toxic. Although it is likely that the other regimens described for HIV-infected patients will work in non-HIV-infected patients, clinical experience is limited. Additional studies are needed to determine whether corticosteroids have a place as adjunctive agents in the treatment of pneumocystosis in non-HIV-infected patients.

The clinical response to anti-*Pneumocystis* drugs is slow, particularly in HIV-infected patients. It is usually prudent to wait at least 8 days for HIV-infected patients and 5 or 6 days for non-HIV-infected patients before considering a change in therapy. Substitution of a drug seems preferable to adding a second agent because there is no evidence that two drugs are more effective than a single agent. A retrospective study has shown that starting antiretroviral therapy early in the treatment of pneumocystosis is associated with improved survival.<sup>114</sup> Clinical deterioration raises the possibility of infection with a second organism and suggests the need for aggressive diagnostic evaluation. The development of respiratory failure requiring mechanical ventilation has traditionally carried a grave prognosis; with improved diagnosis and treatment, the mortality rate has decreased to approximately 40% to 50%.<sup>113,115,116</sup>

Local complications in the management of *Pneumocystis*, such as bullae and pneumatoceles, require careful attention

and follow-up. These lesions lead to a pneumothorax, which presents difficult problems for management.<sup>27,111</sup> A chest tube is helpful but may not fully expand the lung, especially if a bronchopleural fistula develops. Other approaches include pleurodesis with talc or antibiotics and thoracostomy with stapling. Patients with chronic airway disease develop recurrent bacterial pneumonias requiring broad-spectrum antibiotics. Extrapulmonary pneumocystosis should be treated with parenteral drugs.

## PREVENTION AND CONTROL

Prevention of pneumocystosis can be directed either toward the first episode (primary) or toward recurrent episodes (secondary) of the disease. Chemoprophylaxis became widely accepted as the principal preventive measure in HIV-infected patients and other immunocompromised hosts when prospective, controlled clinical trials demonstrated its safety and efficacy.<sup>8</sup> As a general rule, chemoprophylaxis should be continued as long as the risk factors for *Pneumocystis* pneumonia exist. An expert panel developed by the U.S. Public Health Service and Infectious Disease Society of America has published guidelines for the prevention of opportunistic infections in HIV-infected patients.<sup>117</sup> Primary prophylaxis is indicated for all adults and adolescents (including those who are pregnant) infected with HIV who have CD4 counts of less than 200/ $\mu\text{L}$ , unexplained fever ( $>100^\circ\text{F}$ ) for more than 2 weeks, or oropharyngeal candidiasis. Secondary prophylaxis is indicated for all adults and adolescents who have recovered from an episode of pneumocystosis.

TMP-SMX is the drug of choice administered as one double-strength tablet (160 mg TMP plus 800 mg SMX) per day. Alternative regimens with one single-strength tablet (80 mg TMP plus 400 mg SMX) per day or one double-strength tablet three times per week are also satisfactory. In addition to its anti-*Pneumocystis* activity, TMP-SMX prevents bacterial infections and toxoplasmosis. The major problem with TMP-SMX is that up to 40% of HIV-infected patients experience adverse reactions requiring discontinuation of the drug; however, some patients can tolerate reintroduction of TMP by measures such as desensitization.<sup>87</sup>

If TMP-SMX cannot be tolerated, suitable alternatives are dapsone administered at a dose of 100 mg/day or dapsone 50 mg per day plus pyrimethamine 50 mg once a week and leucovorin 25 mg once a week.<sup>117</sup> Other dose regimens of these drugs have also been effective. Atovaquone suspension given at a dose of 1500 mg per day is approximately as effective as the dapsone regimens in *Pneumocystis* prophylaxis. Another option is aerosolized pentamidine 300 mg administered via Respirgard II nebulizer once a month. Aerosolized pentamidine is more expensive and less effective than the other regimens (particularly in patients with CD4 cell counts of less than 100/ $\mu\text{L}$ ); requires negative pressure rooms with adequate ventilation; may increase the frequency of atypical clinical presentations, pneumothorax, or extrapulmonary spread of *Pneumocystis* infection; and should not be used in patients with tuberculosis. Despite these limitations, aerosolized pentamidine is better tolerated than the other regimens. The side effects are cough and bronchospasm, which can be controlled with a  $\beta$ -agonist. Although other anti-*Pneumocystis* drugs (e.g., clindamycin plus primaquine) have

also been considered for prophylaxis, insufficient information is available to make recommendations about their use.

Primary prophylaxis is indicated for children born to HIV-infected mothers, beginning at 4 to 6 weeks of age.<sup>117</sup> Prophylaxis may be discontinued if the child is found not to be infected with HIV, but it should be continued through the first year of life if HIV is found. After this, the need for prophylaxis is based on age-adjusted CD4 counts.

Antiretroviral therapy often results in an increase in CD4 counts. Primary and secondary *Pneumocystis* prophylaxis may be discontinued in adults if the CD4 count remains above 200 cells/ $\mu$ L for more than 3 months.<sup>117</sup> However, HIV patients with a CD4 count greater than 200/ $\mu$ L who have had a prior episode of pneumocystosis should continue chemoprophylaxis indefinitely.

Recommendations for *Pneumocystis* prophylaxis in non-HIV patients are less well defined. Based on the available literature,<sup>112,118</sup> primary prophylaxis should be considered in the following conditions: organ transplantation; severe protein malnutrition; primary immune deficiency diseases; persistent CD4 counts less than 200/ $\mu$ L; and immunosuppressive or cytotoxic therapy for cancer, collagen vascular diseases, and other conditions. If corticosteroids are the sole drug, a reasonable guide to the need for prophylaxis is the equivalent of prednisone 20 mg per day for more than 1 month. Whether prophylaxis is needed for the corticosteroids given for asthma is controversial. Secondary prophylaxis is recommended for all patients as long as the immunosuppressive conditions persist. TMP-SMX is the drug of choice in all non-HIV patients. Although other agents have not been well studied, it is assumed that they will work as well in these patients as they do in HIV patients.

There are no uniform guidelines about isolating patients with pneumocystosis in health care facilities. However, in light of increasing evidence supporting the communicability of pneumocystosis infection in humans,<sup>118</sup> it seems prudent to prevent *Pneumocystis* patients from having direct contact with other immunocompromised hosts.

## Enteric Amebiasis

WILLIAM A. PETRI, Jr  
UPINDER SINGH

### INTRODUCTION

*Entamoeba histolytica* has been reclassified into three genetically distinct but morphologically identical species: the invasive pathogen *E. histolytica* and the noninvasive parasites *E. moshkovskii* and *E. dispar*. *E. histolytica* is the cause of amebic colitis and liver abscess. *E. dispar* is present in many asymptomatic “cyst passers” in developing countries, as well as in sexually active male homosexuals from developed countries. *E. moshkovskii* has recently been recognized to also be a prevalent infection in children in the developing world. Other amebae are less a source of diagnostic confusion as they are morphologically differentiated from the *E. histolytica*/*moshkovskii*/*dispar* group and include *Entamoeba hartmanni*, *Entamoeba coli*, *Entamoeba polecki*, *Entamoeba gingivalis*, *Iodamoeba butschlii*, *Endolimax nana*, and *Blastocystis hominis*. These amebae are usually nonpathogenic commensals and are reviewed briefly.

### AGENT

#### History

A link between dysentery and liver abscess may have been first recognized in 1828 by James Annesley in his two-volume monograph *Prevalent Diseases of India*: “... hepatic disease seems to be induced by the disorder of the bowels, more particularly when this disorder is of a subacute or chronic kind.” Amebae in stool were postulated to be responsible for diarrhea by Lambl in 1855, who described their appearance in the stool of a child from Prague who died of infantile diarrhea.<sup>1,2</sup> Fedor Löscher demonstrated amebae in the stools of a 24-year-old farmer with dysentery from his first clinic visit in November 1873 to his death in April 1874 in Saint Petersburg, Russia. Löscher described the amebae in the stool as having a “round, pear-shaped or irregular form and which are in a state of almost continuous motion.” Autopsy demonstrated colonic ulcerations containing amebae. Dysentery with amebic ulcers in the colon was induced in one dog by repeated inoculations of the patient’s fresh ameba-containing stool orally and rectally.<sup>1,2</sup>

Sir William Osler reported the first North American case of amebiasis in 1890, when he saw a young physician in Baltimore with dysentery. “Dr. B., age 29, resident in Panama

for nearly six years, where he had had several attacks of dysentery, or more correctly speaking a chronic dysentery, came north in May, 1889....” On February 15, 1890, the patient was having six to eight mucoid stools with traces of blood daily, a fever of 103°F, and a tender liver extending “nearly a hand’s breadth above the normal limit.” Amebae were observed in the stool and abscess fluid: “The general character of the amoeba [found in the stool] correspond in every particular with those found in the liver.”<sup>3</sup> A year later, Osler’s colleagues Councilman and Lafleur proceeded through a classic investigation of 14 cases of amebic dysentery to clearly distinguish amebiasis from bacterial dysentery, and coined the terms *amebic dysentery* and *amebic liver abscess*.<sup>4</sup>

Piso introduced ipecac bark, used for centuries in Peru for the treatment of dysentery, to Europe in 1658. Helvetius used ipecac to successfully treat the dysentery of Louis XIV and sold it as a secret remedy to the French government. It was not until 1858 that the use of large doses of ipecac for the treatment of dysentery was promoted by the surgeon E.S. Docker, in Mauritius, who demonstrated that ipecac (60 grains two to three times a day) reduced the death rate from 10%–18% to only 2%. Unfortunately, administration of large doses of ipecac by mouth was complicated by such severe nausea and vomiting as to necessitate the coadministration of opium, chloral hydrate, or tannic acid. Leonard Rogers,<sup>5</sup> a professor of pathology at Calcutta, discovered that emetine, the principal alkaloid in ipecac, would kill amebae in the mucus of stools from patients with dysentery at dilutions as high as 1:100,000. In 1912, he reported the successful treatment of three patients in Calcutta, who had been unable to tolerate oral ipecac, by injection of emetine.<sup>5</sup>

Walker and Sellards<sup>6</sup> in the Philippines in 1913, in human volunteer studies, documented the cyst form of *E. histolytica* as the infective form of the parasite and the life cycle was described by Dobell in 1925. Axenic culture of *E. histolytica* was accomplished by Diamond<sup>7</sup> at the National Institutes of Health (NIH) in 1961, which enabled study of the cell biology and biochemistry of the parasite upon which our modern understanding of amebiasis is based.

### Taxonomy

*E. histolytica* is a pseudopod-forming nonflagellate protozoan parasite. It is the most invasive of the *Entamoeba* group and the only *Entamoeba* to cause amebic colitis and liver abscess. Trophozoites contain a single nucleus, and nuclear division occurs without the formation of condensed metaphase chromosomes. No sexual forms of the parasite have been identified.

*E. histolytica* has recently been reclassified into three species that are morphologically identical but genetically distinct: *E. histolytica* (Schaudinn, 1903), an invasive disease-causing parasite, and *E. dispar* (Brumpt, 1925) and *E. moshkovskii*, both noninvasive parasites. As early as 1925, it was proposed by Brumpt<sup>8</sup> that two morphologically identical species of *Entamoeba*, both of which produced quadrinucleate cysts measuring 10 µm or more in diameter, infected humans. Brumpt found that only one of the species caused disease in

kittens or human volunteers, and named the nonpathogenic species *Entamoeba dispar*. These studies languished in the absence of a means to distinguish the two morphologically identical parasites. It was not until Sargeant and colleagues<sup>9</sup> demonstrated in 1978 that isoenzyme typing could be used to distinguish the pathogenic from the nonpathogenic species of *Entamoeba* that the issue was reexamined.

The invasive species *E. histolytica* and the noninvasive species *E. moshkovskii* and *E. dispar* are morphologically identical but can be differentiated by isoenzyme analysis, typing by monoclonal antibodies to surface antigens, and restriction fragment length polymorphism (Box 86-1).<sup>9-19</sup> Earlier reports that *E. histolytica* and *E. dispar* could convert in culture<sup>20,21</sup> were impossible to reconcile with the genetic differences demonstrated between these two species, and were recently shown to be artifactual, with the apparent conversion due to inadvertent contamination of *E. dispar* cultures with *E. histolytica*.<sup>22</sup>

*E. dispar* and *E. moshkovskii* have never been documented to cause colitis or liver abscess. Because *E. dispar* and perhaps *E. moshkovskii* infection are more common than *E. histolytica* infection<sup>23</sup> and need not be treated, an important clinical

advance has been the development of antigen detection tests that differentiate infection by the two amebae (see Diagnosis).

### Life Cycle

The *E. histolytica* life cycle consists of an infective cyst and an invasive trophozoite form: The invasive trophozoite form is 10 to 60  $\mu\text{m}$  in diameter and has a single nucleus with a central karyosome (Fig. 86-1A), while the cyst is 10 to 15  $\mu\text{m}$  in diameter and contains four or fewer nuclei (Fig. 86-1B). Formation of the cyst appears to involve quorum sensing mediated in part by the parasite cell surface Gal/GalNAc lectin.<sup>24</sup> The quadrinucleate cyst is resistant to chlorination, gastric acidity, and desiccation and can survive in a moist environment for several weeks. Infection with *E. histolytica* occurs when cysts are ingested from fecally contaminated food or water. Excystation occurs in the intestine where a cyst undergoes nuclear fission followed by cytoplasmic division to form eight trophozoites. Trophozoites have the ability to colonize or invade the large bowel while cysts are never found within invaded tissues. Invasion of the intestinal mucosal barrier by

the trophozoite leads to the formation of flask-shaped colonic ulcers. Migration of colonic parasites to the liver is thought to occur via the portal vein. Whether or not infection results in colonization or invasion may be influenced by the *E. histolytica* strain and its interaction with bacterial flora; host genetic susceptibility; and factors such as malnutrition, sex, age, and immunocompetence.

**Cell Biology and Biochemistry**

*E. histolytica* is a eukaryotic organism but lacks organelles that morphologically resemble rough endoplasmic reticulum,

the Golgi apparatus, or mitochondria<sup>25-28</sup> (Fig. 86-2; Box 86-2). The presence of nuclear-encoded mitochondrial genes, such as pyridine nucleotide transhydrogenase and *hsp60*, is consistent with *E. histolytica* having contained mitochondria at one time. Despite the lack of rough endoplasmic reticulum or Golgi apparatus, cell surface and secreted proteins contain signal sequences, and tunicamycin inhibits protein glycosylation.<sup>26</sup> Ribosomes form aggregated crystalline arrays in the cytoplasm of the trophozoite. Biochemical pathways differ from metazoans in the lack of glutathione and enzymes required for glutathione metabolism, the use of pyrophosphate instead of adenosine triphosphate (ATP) at several steps in glycolysis, and the inability to synthesize purine nucleotides de novo. Glucose is actively transported into the cytoplasm, where the end products of carbohydrate metabolism are ethanol, CO<sub>2</sub>, and, under aerobic conditions, acetate.<sup>25</sup>

**Gene Structure and Organization**

*E. histolytica* genomic organization and promoter elements appear to be distinct from both metazoan and better-characterized protozoan organisms. The lack of mitochondria in *E. histolytica* and recombinant DNA (rDNA) sequence analysis<sup>26</sup> suggest that this organism is a primitive eukaryote related to *Dictyostelium*. However, phylogenetic analysis of the elongation factor 1 $\alpha$  gene<sup>27</sup> and mitochondrial enzyme genes found within the *E. histolytica* genome<sup>28</sup> are consistent with *Entamoeba* having lost mitochondria and being more closely related to *Euglena gracilis* or *Trypanosoma cruzi*.

The sequencing of the HM1:IMSS strain of *E. histolytica* is near completion in a joint effort of the Institute for Genomic Research and the Sanger Center. Many aspects of *E. histolytica* gene organization and transcription are unusual.<sup>29</sup> Up to 50% of the genome is comprised of repetitive elements including

**FIGURE 86-1** *Entamoeba histolytica* trophozoite and cyst. *A*, The motile and invasive trophozoite form contains a single nucleus and is 10 to 60  $\mu$ m in diameter. *B*, The infectious cyst form is 10 to 15  $\mu$ m in diameter and contains four nuclei. Note that it is not possible to distinguish *E. histolytica* from *E. dispar* morphologically. (Courtesy of Centers for Disease Control and Prevention, Atlanta, GA.)

**FIGURE 86-2** Electron micrograph of an *Entamoeba histolytica* trophozoite. Note the nucleus with peripheral and central chromatin, the lack of structures resembling mitochondria or rough endoplasmic reticulum, and the prominent intracytoplasmic vacuoles.

unusual tandem repeats of tRNA and 5s rRNA genes as well as retrotransposon-like elements. The genome is relatively small for a eukaryote ( $3.2 \times 10^7$  bp) and extremely AT-rich (67% within coding regions and 78% overall<sup>29,30</sup>). Transcription of protein-encoding genes is by an RNA polymerase which is resistant to 1 mg/mL  $\alpha$ -amanitin.<sup>31</sup> Introns appear to be present in only 20% of genes.<sup>32,33</sup> There is no evidence of transplicing or polycistronic transcription.<sup>34</sup> However, coding

regions are tightly packed, with small intergenic regions.<sup>34</sup> The structure of messenger RNA (mRNA) is remarkable as well, with the 5'-untranslated region having an average length of 11 bases compared to a metazoan average of 60 to 80 bases.<sup>35</sup> The 3'-untranslated region is also short, with an average size of only 33 bases.<sup>34</sup> Ribosomal RNA (rRNA) is not contained within the genome but is encoded on a circular, 24-kb DNA episome.<sup>36</sup>

Both transient and stable DNA-mediated transfection of *E. histolytica* with heterologous gene expression have been recently accomplished (Fig. 86-3). Deletion and replacement analysis has been conducted on the promoter of the *E. histolytica* gene encoding the heavy subunit of the N-acetyl- $\beta$ -D-galactosamine-specific adhesin (*hgl5*).<sup>37</sup> Four positive upstream regulatory elements and one negative upstream regulatory element were identified in the 200 bases upstream of the start of transcription (Fig. 86-4). The transcription factors that control gene expression by these upstream regulatory elements have been identified in two cases. Both transcription factors are novel, with one containing RNA-binding motifs and the other EF-hand motifs.<sup>38,39</sup> Strikingly, the ability of the EF-hand containing transcription factor to bind to its cognate DNA motif is controlled by calcium.<sup>39,40</sup> Core promoter elements, including a TATA element at 30 bp upstream of the transcription start site, the novel conserved sequence GAAC, which is located between the TATA and initiator elements, and the conserved sequence at the transcription start site (putative initiator), have been demonstrated to regulate gene expression and control the site of transcription initiation.<sup>41,42</sup>

## EPIDEMIOLOGY

The distribution of *E. dispar* is worldwide, while the preponderance of *E. histolytica* infection, morbidity, and mortality is experienced in Central and South America, Africa, and the Indian subcontinent. The epidemiology of amebiasis is being re-examined in light of the recently appreciated distinction between *E. histolytica*, *E. moshkovskii*, and *E. dispar*. Surveys that determined prevalence of infection by examining stool for parasites may have measured predominantly *E. dispar* and *E. moshkovskii* as these species are more common, while serologic surveys reflected the incidence of *E. histolytica* infection, as *E. dispar* and *E. moshkovskii* infection do not result in a positive serologic test.<sup>43</sup>

Two recent studies from the developing world using modern diagnostic tests have highlighted the burden of amebic disease. In Dhaka, Bangladesh, preschool children had a 2.2% annual frequency of amebic dysentery as compared to a 5.3% rate of *Shigella* dysentery during 3 years of prospective community observation.<sup>44</sup> An annual incidence of amebic liver abscess of 21 cases/100,000 inhabitants was observed in Hue City, Vietnam.<sup>45</sup> The 1987–1988 Mexican national survey of 67,668 serums (acquired by a probabilistic sampling technique from a representative cross-section of the country) demonstrated a 8.4% seropositivity for *E. histolytica* as measured with the indirect hemagglutination assay (IHA).<sup>46</sup> Peak seropositivity was 11% in the 5- to 9-year-old age group. In the year of the serosurvey there was an estimated 1 million cases of amebiasis and 1216 deaths due to *E. histolytica* infection in Mexico.<sup>47</sup>

### Box 86-2 Some Unusual Features of the Cell Biology and Biochemistry of *Entamoeba histolytica*

- Lack of mitochondria, rough endoplasmic reticulum, or Golgi apparatus
- Presence of crystalline arrays of aggregated ribosomes
- Ribosomal RNA genes on multicopy circular DNA molecules
- Lack of glutathione and enzymes of glutathione metabolism
- Use of pyrophosphate instead of adenosine triphosphate at several steps in glycolysis
- Inability to synthesize purine nucleotides de novo

**FIGURE 86-3** The two-promoter transfection vector pTCV3. The actin promoter is used to express *neo*, enabling selection of stably transfected parasites with the antibiotic G418. The lectin *hgl* promoter is used to express a gene of interest in the stably transfected amebae, which in this case is firefly luciferase.

Residents of developed nations such as the United States that are at higher risk of developing amebiasis include, most importantly, immigrants from or travelers to countries where amebiasis is endemic,<sup>48–51</sup> sexually active male homosexuals (who are predominantly infected with *E. dispar*<sup>52,53</sup>), and residents of institutions for the mentally retarded.<sup>54</sup> A total of 2970 cases of amebiasis in the United States were reported to the Centers for Disease Control and Prevention in 1993 (the last year that it was a reportable disease); 33% of the patients were Hispanic and 17% Asian or Pacific Islanders.<sup>55</sup>

Amebic liver abscess is 7 to 12 times more common in men, although in children the sex distribution is equal.<sup>56,57</sup> More severe disease is seen in the very young and old, the malnourished, and pregnant women.<sup>58–61</sup> *E. histolytica* infection in human immunodeficiency virus (HIV)-infected children was clustered in the most severely malnourished children with chronic diarrhea in a study from Tanzania.<sup>62</sup>

The typical patient in the United States with amebic liver abscess is a Hispanic male between the ages of 20 and 40 years. Infection with *E. histolytica* generally presents clinically within a year of immigration to the United States, although it is not rare for presentation to lag immigration by up to 12 years.

Travelers to the tropics are at low but definite risk of acquiring amebic infection: one study of 2700 German citizens returning from tropical areas demonstrated a 4% incidence of *E. histolytica*/*E. dispar* infection.<sup>51,63,64</sup> Diarrhea and detection of *E. histolytica* only (no other intestinal pathogens present) occurred in 80% of travelers with pathogenic *E. histolytica*.<sup>51</sup>

## DISEASE

### Asymptomatic Colonization

Noninvasive intestinal infection is apparently the only presentation of *E. dispar* and *E. moshkovskii* infection and is also a common presentation of *E. histolytica* infection (Box 86-3). Patients may have some ill-defined gastrointestinal complaints, but for the most part tolerate the infection well. Colonization with *E. dispar* and *E. moshkovskii* does not require intervention on the part of the physician, as these amebae have never been identified as a cause of colitis or abscess. In contrast, patients colonized with *E. histolytica* are at risk of future (months to even years later) development of invasive disease and should be treated if coincidentally diagnosed.<sup>65</sup> Antigen detection tests to distinguish *E. histolytica*

**FIGURE 86-4** Structure of the promoter of the *hgl5* gene of *Entamoeba histolytica*. Four positive and one negative upstream regulatory regions have been identified by linker scanner mutagenesis and transient transfection system using the reporter gene luciferase. Three regions have also been identified in the core promoter which appear to control gene expression.

from *E. dispar* and *E. moshkovskii* infection are commercially available for clinical use (see Diagnosis).

Almost all *E. histolytica*/*moshkovskii*/*dispar* isolates from colonized homosexual males in Europe and the United States are *E. dispar*<sup>52,65–67</sup>; this explains the general lack of invasive amebiasis in this population at risk of HIV infection. In patients with HIV infection, no correlation has been established between the presence of *E. dispar* and gastrointestinal symptoms, and apparently antiamebic treatment is not warranted. In Japan the situation is different: 13% to 20% of homosexual men are seropositive for *E. histolytica* infection, the organism has been isolated from the stools of homosexual men, and cases of invasive amebiasis have been reported in homosexual and HIV-infected males.<sup>68–70</sup> This indicates the need for a more aggressive approach to the management of intestinal amebic infection in homosexual males in Japan, and demonstrates the potential for spread of pathogenic *E. histolytica* to the homosexual populations of other nations.

**Dysentery and Colitis**

The major concern of the physician confronted with a patient with dysentery (diarrhea that contains visible or microscopic blood) is to differentiate between infectious causes (including amebiasis, *Shigella*, *Salmonella*, *Campylobacter*, and enteroinvasive and enterohemorrhagic *Escherichia coli*) and noninfectious causes (including inflammatory bowel disease, ischemic colitis, and gastrointestinal bleeding secondary to arteriovenous malformations or diverticulitis).<sup>70</sup> It is at times difficult to make the diagnosis of amebic colitis, as the presentation of the illness may be insidious or chronic, bleeding may occur without diarrhea, and fever is an unusual finding. A single stool examination for parasites is insensitive, histopathologic confirmation of infection on biopsy specimens may be

difficult, and serologic tests for antiamebic antibodies are not always positive in the acute setting (Table 86-1).

In a developed country such as the United States, most patients with amebiasis will be immigrants or travelers from areas with endemic amebiasis. Patients with amebic colitis typically present with a history over several weeks of gradual onset of abdominal pain and tenderness, diarrhea, and bloody stools. In one series, patients with amebic colitis had an average duration of prehospital illness of 21 days, compared with 4 days for patients with shigellosis.<sup>71</sup> Because of the gradual onset, weight loss is a common finding. Surprisingly, fever is present in only the minority (8% to 38%) of patients with amebic colitis.<sup>71,72</sup> Examination of stools reveals that they are uniformly positive for occult blood; microscopic examination of stool for *E. histolytica* cysts and trophozoites is very insensitive: A single examination is positive in only one-third to one-half of cases, with three or more examinations required in most cases to identify the organism. Stool antigen detection (the TechLab *E. histolytica* II Test) and PCR are more sensitive than microscopy and are the only tests specific for *E. histolytica* infection.<sup>72</sup> Colonic lesions can vary from only mucosal thickening, to flask-shaped ulcerations, to necrosis of the intestinal wall (Fig. 86-5).

Unusual manifestations of amebic colitis include acute necrotizing colitis, ameboma (granulation tissue in colonic lumen mimicking colonic cancer in appearance), cutaneous amebiasis, and rectovaginal fistulas. Acute fulminant or necrotizing colitis is the most feared complication, occurs in about 0.5% of cases, may require surgical intervention, and has a mortality greater than 40%.<sup>73,74</sup> Abdominal pain, distention, and rebound tenderness are present in most patients with fulminant colitis, although frank guarding is uncommon.

Indications for surgery in fulminant amebic colitis include free extraperitoneal perforation, failure of a perforation with a localized abscess to respond to antiamebic drugs, and perhaps persistence of abdominal distention and tenderness while on antiamebic therapy. With localized colonic disease, partial colectomy with exteriorization of the ends is recommended over primary anastomosis, as anastomoses may fail due to the friable condition of the bowel wall. Better surgical results for extensive disease have been achieved with total colectomy with exteriorization of the proximal and distal ends.<sup>73,74</sup>

### Liver Abscess

A typical patient with an amebic liver abscess in the United States is an immigrant, usually a Hispanic male, 20 to 40 years old. A 1- to 2-week history of fever and abdominal pain is common. Signs of amebic liver abscess include right upper quadrant pain, fever of 38.5°C to 39.5°C, leukocytosis, abnormal serum transaminases and alkaline phosphatase, an elevated right hemidiaphragm, and a defect on hepatic imaging study<sup>56,57,75,76</sup> (Table 86-2; Fig. 86-6). A more chronic presentation of 2 to 12 weeks of weight loss, fever, and abdominal pain has been reported in a subset of patients with single abscesses.<sup>57</sup> Roughly 90% of patients with liver abscess are males, although in children (especially infants<sup>77,78</sup>) the sex distribution is equal. The abscess is single and in the right lobe of the liver 80% of the time. However, the most common location for a pyogenic abscess is also in the right lobe, so the location is not helpful in distinguishing the cause of an abscess.<sup>79,80</sup> Patients with pyogenic, as opposed to amebic, liver abscesses are more likely to be older than 50 years, present with jaundice, pruritis, sepsis, or shock, and have a palpable mass.<sup>81</sup>

Most patients with liver abscess do not have concurrent colitis, although a history of dysentery within the last year can sometimes be obtained. Amebae are infrequently identified microscopically in the stool (18% of cases) at the time of diagnosis of liver abscess, although they can be identified in the stool by culture in the majority of patients. Liver abscess can present acutely with fever, right upper abdominal tenderness and pain, or subacutely with prominent weight loss, fever, and abdominal pain. The peripheral white blood cell count and alkaline phosphatase level are often elevated. Chest radiograph demonstrates elevation of the right hemidiaphragm in most patients.<sup>82,83</sup> Early evaluation of the hepatobiliary system with ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) is essential to demonstrate the abscess in the liver.

The differential diagnosis of the lesion in the liver would include pyogenic abscess (less likely if the gallbladder and intrahepatic ducts appear normal), hepatoma, and echinococcal cyst (unlikely to present acutely with fever and abdominal pain).

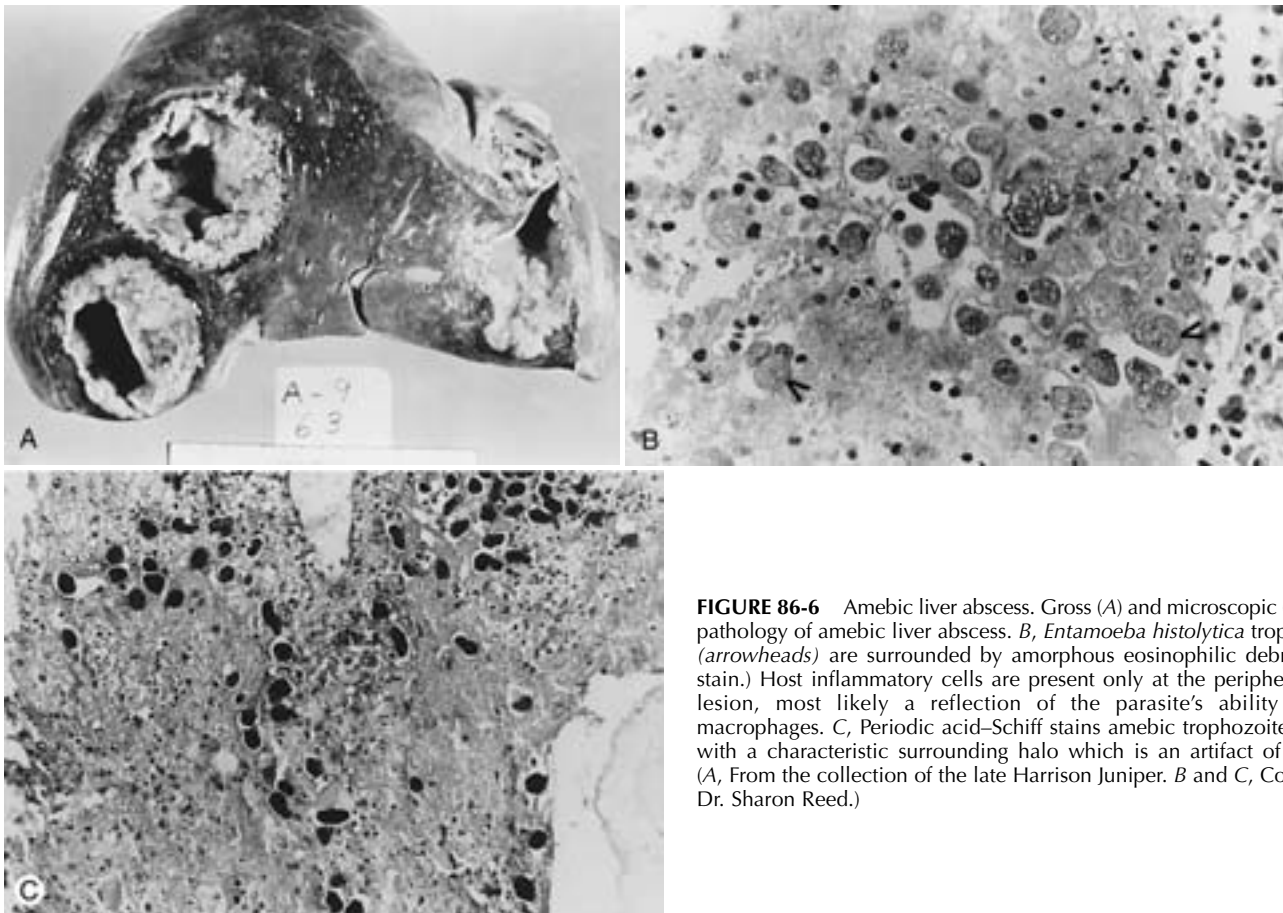

Aspiration of the abscess is occasionally required to diagnose amebiasis. The lack of bacterial infection in the abscess fluid is most helpful in ruling out a pyogenic abscess; amebae are rarely visualized in the pus in only the minority of cases but PCR for *E. histolytica* appears to be very sensitive. Antibodies to *E. histolytica* are present in the serum of 92% to 97% of patients on acute presentation with amebic liver abscess, and therefore are very useful diagnostically. Because a significant proportion of the population in developing countries is seropositive, antibody tests are less specific in residents or immigrants from the developing world (see Diagnosis).

Severe amebic liver abscess, defined in one study as an abscess that ruptures despite at least three days of antiamebic treatment or an abscess complicated by secondary bacterial infection, may be associated with dyspnea, elevated right hemidiaphragm and pleural effusion, jaundice, anemia, and diabetes mellitus.<sup>83,84</sup> Patients with findings associated with more severe disease might benefit from early drainage. Intrathoracic and intraperitoneal rupture of an amebic liver

**Table 86-2** Symptoms and Signs of Amebic Liver Abscess

Symptoms and Signs	Range

**FIGURE 86-6** Amebic liver abscess. Gross (A) and microscopic (B and C) pathology of amebic liver abscess. B, *Entamoeba histolytica* trophozoites (arrowheads) are surrounded by amorphous eosinophilic debris. (H&E stain.) Host inflammatory cells are present only at the periphery of the lesion, most likely a reflection of the parasite's ability to lyse macrophages. C, Periodic acid-Schiff stains amebic trophozoites darkly, with a characteristic surrounding halo which is an artifact of fixation. (A, From the collection of the late Harrison Juniper. B and C, Courtesy of Dr. Sharon Reed.)

abscess can be adequately treated with antiamebic therapy without surgery if secondary bacterial infection is absent.<sup>83</sup>

Unusual extraintestinal manifestations of amebiasis include direct extension of the liver abscess to pleura or pericardium, brain abscess, and genitourinary amebiasis.

## PATHOGENESIS

Carbohydrate-protein interactions play a key role in human infection by the *E. histolytica*.<sup>84</sup> Killing of host cells by *E. histolytica* trophozoites in vitro occurs only on direct contact (Fig. 86-7), which is mediated by an amebic adhesin which recognizes N- and O-linked oligosaccharides.<sup>85-91</sup> This amebic Gal/GalNAc lectin is a heterodimer of heavy and light subunits noncovalently associated with an intermediate subunit, all of which are encoded by multigene families designated *hgl*, *lgl*, and *igl*, respectively.<sup>85-91</sup> Apposition of amebic and target cell plasma membranes, as can be achieved by centrifugation of target cells and amebae into a pellet, will not lead to cytolysis if the amebic lectin is inhibited with Gal/GalNAc. This indicates that the lectin not only mediates adherence, but also participates in the cytolytic event. Antilectin monoclonal antibodies (mAbs) directed against epitope 1 of the lectin-heavy subunit block cytotoxicity but not adherence, implicating the lectin in the cytotoxic as well

as adherence events. Antilectin antibodies that block cytotoxicity also cause a conformational change in the lectin, which increases carbohydrate binding capacity. One could speculate that such antibodies block cytotoxicity by preventing a second conformational change in the lectin required for cell killing.

The first receptor encountered by the lectin may be the human colonic mucin layer of the large intestine.<sup>92</sup> Binding of the lectin to colonic mucins is Gal/GalNAc-inhibitable and of very high affinity (dissociation constant of  $8.2 \times 10^{-11} \text{ M}^{-1}$ ). Interaction of trophozoites with colonic mucins appears to be a dynamic process, with trophozoites both inducing the secretion of, and degrading, colonic mucins.<sup>92</sup> The mucin layer may protect the host from contact-dependent cytotoxicity of the parasite by binding to and neutralizing the lectin, while at the same time serving as a site of attachment for the parasite to colonize the large bowel.

Invasion of the colon and hematogenous spread to the liver results in the continuous exposure of the extracellular trophozoite to the human complement system. Virulent *E. histolytica* isolated from patients with invasive amebiasis activates the alternative complement pathway but is resistant to C5b-9 complexes deposited on the membrane surface.<sup>93</sup> Resistance to lysis by the membrane attack complex of complement suggested the presence of a C5b-9 inhibitory molecule

**FIGURE 86-7** Killing of a human polymorphonuclear neutrophil (N) by an ameba (A). On establishing contact with the ameba, the neutrophil undergoes membrane blebbing and loss of granules and cytoplasmic integrity. (Magnification 2000 $\times$ .) (From Ravdin JI, Guerrant RL: Current problems in diagnosis and treatment of amebic infections. *Curr Clin Top Infect Dis* 7:82–111, 1996.)

in the amebic surface. This C5b-9 inhibitory molecule was identified as the Gal/GalNAc lectin by screening for monoclonal antibodies that increased *E. histolytica* lysis by serum and purified complement.<sup>94</sup> Examination of the sequence of the 170-kD subunit showed limited identity with CD59, a human inhibitor of C5b-9 assembly, and the purified lectin was recognized by anti-CD59 antibodies. The lectin bound to purified human C8 and C9, and blocked assembly in the amebic membrane of the complement membrane attack complex at the steps of C8 and C9 insertion. Reconstitution of the lectin from serum-resistant into serum-sensitive amebae conferred resistance to the membrane attack complex, a direct demonstration of its C5b-9 inhibitory activity. The lectin therefore appears to function not only in adherence and host cell killing, but also in evasion of the complement system of defense via a remarkable mimicry of human CD59.<sup>94</sup> Recent evidence points to the cytoplasmic domain of the lectin in controlling lectin activity by inside-out signaling, through a region with homology to  $\beta_2$  integrins.<sup>95</sup>

Contact-dependent killing by *E. histolytica*, after evasion of the colonic mucin layer, has been the subject of intensive investigation. Intracellular calcium in target cells rises approximately 20-fold within seconds of direct contact by an amebic

trophozoite and is associated with membrane blebbing.<sup>96</sup> Cell death occurs 5 to 15 minutes after the lethal hit is delivered. Extracellular ethylenediaminetetraacetate (EDTA) and treatment of the target cells with the slow sodium-calcium channel blockers verapamil and bepridil<sup>97</sup> significantly reduce amebic killing of target cells in suspension. Murine myeloid cells killed by *E. histolytica* undergo a process of death that morphologically resembles the programmed cell death seen with growth factor deprivation and is associated with a nucleosomal pattern of DNA fragmentation. Apoptotic death is followed by ingestion of the host cell.<sup>98</sup>

Isolation of an amebic pore-forming protein similar in function to pore-forming proteins of the immune system has been reported.<sup>99</sup> A purified 5-kD amoebapore and a synthetic peptide based on the sequence of its third amphipathic  $\alpha$  helix have recently been shown to have cytolytic activity for nucleated cells at high concentrations (10 to 100  $\mu$ M).<sup>99</sup> Interaction with the extracellular matrix may be mediated by fibronectin, laminin, and collagen receptors.<sup>100,101</sup> Proteolytic activities, such as the collagenase contained within electron-dense granules in the amebic cytoplasm, are also believed to be involved in damage to cells and the extracellular matrix of the host. Secreted amebic cysteine proteases cause a cytopathic

(as opposed to cytotoxic) effect manifest by cells being released from monolayers in vitro without cell death.<sup>102</sup> In vivo validation of the role of the lectin, cysteine proteinases, and amebapore has recently been accomplished by reverse genetic techniques.<sup>103-106</sup>

## IMMUNITY

Immunity to infection is associated with a mucosal IgA response against the carbohydrate recognition domain of the Gal/GalNAc lectin: children with this response had 86% fewer new infections over one year of prospective observation<sup>107,108</sup> (Fig. 86-8).

Several lines of evidence suggest an important role for cell-mediated immunity, via cytokine activation of macrophages and neutrophils, to kill amebae. In animal models, interventions that resulted in a depression of cellular immunity, such as neonatal thymectomy, splenectomy, steroid treatment, radiation, silica therapy, and antimacrophage or anti-lymphocyte globulin, resulted in enhanced amebic liver abscess. Lymphocytes from patients recovered from invasive amebic disease developed cell-mediated immune responses in vitro against total *E. histolytica* extracts. These responses included T-cell proliferation, amebicidal activity, and interleukin-2 (IL-2) and interferon- $\gamma$  (IFN- $\gamma$ ) production.<sup>109-113</sup> Human macrophages and neutrophils, activated with IFN- $\gamma$  and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), are endowed with the capability of killing *E. histolytica* trophozoites, while in the absence of IFN- $\gamma$ , these effector cells were killed by the amebae. In murine macrophages, TNF- $\alpha$  was shown to play a central role in activating macrophages for nitric oxide-dependent cytotoxicity against *E. histolytica*. A CD4 T cell-mediated immune

response may not always be protective: In the murine model of amebic colitis depletion of CD4 T cells has been shown to ameliorate inflammation and colonic ulceration.<sup>114</sup>

The association of anti-parasite IgA antibody with in vivo resistance to infection, as well as the ability of pro-inflammatory cytokines to activate protective immunity in vitro suggested that MHC class II alleles could affect both the acquisition of amebiasis and its disease burden. To test this hypothesis, class II genotype frequencies were determined among a cohort of unrelated Bangladeshi children who had been followed every other day for 3 years for *E. histolytica* infection. Individuals heterozygous for the DQB1\*0601/ DRB1\*1501 haplotype were 10.1 times (95% CI: 2.02, 50.6) more likely not to have been infected with *E. histolytica*. Other DQB1 and DRB1 alleles (DQB1\*0202, DQB1\*0301, DRB1\*0701) showed no evidence of association with any of the clinical outcomes related to amebiasis. This potential protective association may offer insight into why amebiasis does not occur in some children exposed to the parasite, and implicates class II restricted immune responses in protection from *E. histolytica* infection.<sup>115</sup>

## DIAGNOSIS

See Table 86-3 for a summary of test sensitivity for amebiasis diagnosis.

## Microscopy

Microscopic identification of the parasite in stool, liver abscess pus, or colonic biopsies is neither sensitive nor

**FIGURE 86-8** Acquired immunity to amebiasis in children. Children who developed stool IgA anti-CRD (Lectin Carbohydrate Recognition Domain) antibodies in the first year of the study ( $n = 81$ ) had a lower incidence of new *E. histolytica* infections in the second year compared to children who remained IgA anti-CRD negative ( $n = 149$ ). The two groups are statistically significantly different ( $p \leq 0.04$ ) at every time point. (From Haque R, Duggal P, Ali IM, et al: Innate and acquired resistance to amebiasis in Bangladeshi children. *J Infect Dis* 186:547-552, 2002.)

**Table 86-3** Sensitivity of Tests for Diagnosis of Amebiasis

Test	Colitis	Liver
Microscopy (stool)	25%–60%	10%–40%
Stool antigen detection	>90%	~40%
Serum antigen detection	65% early	~100% prior to treatment
Microscopy (abscess fluid)	N/A	≤20%
Abscess antigen detection	N/A	~40%
Serology (indirect hemagglutination)		
Acute	70%	70%–80%
Convalescent	>90%	>90%

From Haque R, Huston CD, Hughes M, et al: Current Concepts: Amebiasis. *New Engl J Med* 348:1565–1573, 2003.

specific and should be replaced with *E. histolytica*-specific diagnostic tests (see following discussion). Microscopic examination of a single stool specimen for amebic cysts and trophozoites in a patient with amebic colitis is no more than 33% to 50% sensitive, and in most cases is unable to distinguish pathogenic *E. histolytica* from the morphologically identical nonpathogenic *E. moshkovskii* and *E. dispar* (formerly called the nonpathogenic zymodemes of *E. histolytica*).<sup>116</sup> Erythrophagocytic amebae are more likely to be *E. histolytica* than *E. dispar*, but *E. dispar* trophozoites have also been found to contain ingested red blood cells. Repeated stool examinations in patients with amebic liver abscess were able to detect the parasite in only 8% to 44% of cases.<sup>79</sup> Identification of the parasite in aspirated pus from liver abscesses, even in the most experienced hands, is only 20% sensitive.<sup>70</sup>

### Antigen Detection

A stool antigen detection test that is specific for *E. histolytica* is now commercially available for clinical use from TechLab, Inc. (Blacksburg, VA)<sup>72</sup> (Fig. 86-9). The *E. histolytica* antigen test is rapid, has improved sensitivity compared to microscopy, and is of comparable sensitivity to culture or PCR analysis. The TechLab *E. histolytica* test is based on detection of the Gal/GalNAc lectin in stool. A test to detect the Gal/GalNAc lectin in serum appears promising for the diagnosis of amebic liver abscess (a situation in which it is more difficult than amebic colitis to demonstrate the parasite in stool), with a reported sensitivity in initial tests of 67%.<sup>72</sup>

### Polymerase Chain Reaction

Polymerase chain reaction (PCR), based on amplification of the small subunit rRNA gene, can now be used to identify *E. histolytica* in stool samples. PCR and antigen detection had comparable sensitivities when performed on fresh stool samples, identifying 87% and 85% of *E. histolytica* infections subsequently identified by isoenzyme analysis.<sup>72</sup> PCR detection of *E. histolytica* DNA in both stool and liver abscess pus is a

sensitive test.<sup>117–119</sup> Use of PCR can also be used also to distinguish among isolates of *E. histolytica*, which should prove useful for epidemiologic purposes as well as in determining the virulence characteristics of different isolates.<sup>108,120,121</sup>

### Serology

The IHA test for antiamebic antibody is 70% sensitive early in the illness, to greater than 95% sensitive on convalescence, for the diagnosis of amebic liver abscess and amebic colitis.<sup>70</sup> Most recent reports of series of patients with liver abscess and colitis bear these numbers out. Early in the course of amebic liver abscess the IHA test may be negative.

The major problem with current serologic tests is that they remain positive for years after an episode of amebiasis. As a result, a substantial number (between 10% and 35%) of residents of developing countries have antiamebic antibodies detected by current serologic tests.<sup>122–124</sup> Since the vast majority of patients with invasive amebiasis in developed countries are immigrants from developing nations, serologic tests may not be as specific as one would hope. For example, in five recent series of patients in the United States with amebic liver abscess, between 80% and 96% of patients were immigrants. Therefore current serologic tests may be inadequate for the differentiation of acute from past amebiasis, even in developed nations, and one should not make the diagnosis of amebiasis in a native of a country where amebiasis is endemic on the basis of a serologic test alone.

### Colonoscopy

Colonoscopy is preferable to sigmoidoscopy because disease may be localized to the cecum or ascending colon. Cathartics or enemas should not be used to prepare the

**FIGURE 86-9** Antigen detection test for *Entamoeba histolytica* in stool. Stool specimens with culture-confirmed *E. dispar* (squares) or *E. histolytica* (solid circles) infection, or stools with no detectable *Entamoeba* detected by microscopy (open circles), were assayed using an enzyme-linked immunosorbent assay containing monoclonal antibody specific for *E. histolytica*.

patient because they will interfere with the identification of the parasite. Wet preparations of material aspirated or scraped from the base of ulcers should be examined for motile trophozoites and tested for *E. histolytica* antigen. The appearance of amebic colitis may resemble that of inflammatory bowel disease, with granular, friable, and diffusely ulcerated mucosa. Large geographic ulcers and pseudomembranes may also be present.<sup>125–127</sup> The detection rate of trophozoites upon histopathologic examination of colonic biopsy specimens from patients with amebic colitis varies in different reports from all to only some of the patients.<sup>126–128</sup> Biopsy specimens should be taken from the edge of the ulcers. Periodic acid–Schiff stains the parasites a magenta color (see Fig. 86-6), increasing the ease of detection in biopsies. *E. histolytica* has been shown to invade into carcinomas, causing diagnostic confusion.<sup>128</sup>

### Imaging Procedures

Ultrasound, CT, and MRI studies of the liver are equally sensitive at detecting amebic abscesses (Fig. 86-10). All three

techniques are incapable of differentiating an amebic from a pyogenic abscess.<sup>129–132</sup> At 6 months' follow-up, only one-third to two-thirds of amebic liver abscesses had disappeared upon reultrasonography.<sup>129–132</sup>

### TREATMENT

Colonization with *E. histolytica* should be treated with a luminal agent alone; *E. dispar* and *E. moshkovskii* infection does not require treatment. Drugs effective against luminal infection include diloxanide furoate and paromomycin. Both agents are relatively well tolerated; the recommended duration of treatment with paromomycin is 7 days and with diloxanide furoate, 10 days.<sup>133,134</sup>

Invasive amebiasis (colitis, liver abscess, etc.) should be treated with metronidazole plus a luminal agent. The majority of patients with amebic liver abscess defervesce after 3 to 4 days' treatment with metronidazole. Metronidazole resistance has not yet been reported. Chloroquine, dehydroemetine, and percutaneous drainage of the liver abscess have all been

**FIGURE 86-10** Imaging of hepatic amebic abscess from different patients. *A*, Ultrasound. *B* and *C*, Computed tomography. (*A*, From Ahmed L, El Rooby A, Kassem MI, et al: Ultrasonography in the diagnosis and management of 52 patients with amebic liver abscess in Cairo. *Rev Infect Dis* 12:330, 1990. *B*, From Radin DR, Ralls PW, Colletti PM, et al: CT of amebic liver abscess. *AJR* 150:1297, 1988.)

successfully added to metronidazole treatment for the rare patient not responding to metronidazole alone.<sup>135–137</sup> In most cases of liver abscess, percutaneous drainage is not required and does not speed recovery.<sup>136,137</sup> Metronidazole does not eliminate intestinal colonization in up to 50% of patients with invasive amebiasis unless therapy is prolonged for a minimum of 10 days. With shorter courses of metronidazole therapy, patients may suffer a relapse of invasive infection months later. For this reason the addition of a luminal agent is recommended.<sup>70</sup>

## VACCINE DEVELOPMENT

Prevention of amebiasis at present requires interruption of the fecal-oral spread of the infectious cyst stage of the parasite by improved hygiene, sanitation, and water treatment. On the horizon is the development of a vaccine to prevent disease in residents of and travelers to the developing world. Both the Gal/GalNAc adherence lectin and the serine-rich antigen have proved effective in the prevention of liver abscess in the gerbil model of the disease.<sup>138–141</sup> Only the Gal/GalNAc lectin has been demonstrated to prevent intestinal infection with *E. histolytica*.<sup>139</sup> As opposed to the highly variable serine-rich antigen, the Gal/GalNAc lectin is highly conserved between isolates of *E. histolytica*.<sup>86</sup> Because mucosal IgA anti-Gal/GalNAc lectin antibody is a surrogate marker of the immune state in humans, vaccine design efforts are currently focused on means of mucosal immunization.<sup>142,143</sup>

## OTHER INTESTINAL PROTOZOA

See Figure 86-11 for a summary of intestinal protozoa. *E. gingivalis* was the first parasitic ameba of humans to be described and has subsequently been isolated from a variety of human body sites, including teeth (pyorrhea alveolaris), tonsillar crypts, mucus, and vaginal and cervical smears in women with intrauterine devices.<sup>144</sup> It has been designated to be nonpathogenic and its presence in any of the aforementioned sites does not require treatment. Morphologically, it is identical to *E. histolytica*, with trophozoites that range from 5 to 25  $\mu\text{m}$  (average 10 to 15  $\mu\text{m}$ ). It has a single nucleus with peripheral chromatin, and a small, well-defined karyosome that is usually centrally located. Ingested leukocytes and epithelial cells are often seen in *E. gingivalis*, which is a unique finding in that it is the only species of ameba to ingest leukocytes. No cyst form of the parasite has been identified.<sup>145</sup>

*Entamoeba coli* is a nonpathogenic protozoan with a wide human distribution. The presence of this organism in a patient's stool is a useful indication of fecal-oral exposure. The life cycle of *E. coli* is identical to that of *E. histolytica*, and the two organisms can be found concurrently in up to 10% to 30% of patients in endemic areas. However, *E. coli* is nonpathogenic and requires no specific treatment. The cysts and trophozoites of *E. coli* can be distinguished from those of the pathogenic *E. histolytica* on the basis of nuclear morphology and cyst size. Whereas *E. histolytica* cysts usually have fewer than five nuclei and are 10 to 15  $\mu\text{m}$  in diameter, the cysts of *E. coli* are greater than 15  $\mu\text{m}$  and often have five to eight nuclei.<sup>146–148</sup>

*Entamoeba polecki* is an intestinal protozoan that can be found in monkeys and pigs. Although in rare instances it has been reported to cause human infections, the pathogenic

potential of this protozoan is at present unclear. Studies have reported that up to 19% of children in Papua, New Guinea, are colonized.<sup>149</sup> Although routine treatment is not currently recommended, good clinical response has been reported with metronidazole and diloxanide furate. Most infected persons are asymptomatic, but heavy burdens with this parasite can produce nonspecific gastrointestinal symptoms such as diarrhea, cramps, anorexia, and malaise. The trophozoite form of *E. polecki* resembles that of *E. histolytica* and *E. coli* and differentiation from these and other protozoa rely on identification of the cyst stage of the organism, which is characteristically uninucleate with a large karyosome.<sup>144–148</sup>

*Endolimax nana* is a nonpathogenic commensal parasite with a worldwide distribution that commonly infects humans. It has the same life cycle as *E. histolytica* and is transmitted through oral-fecal spread and poor sanitary conditions. In the tropics it may be identified in the stool of as many as 10% to 33% of persons but requires no specific treatment. It can be distinguished from *E. histolytica* on the basis of its small size (cyst, 6 to 10  $\mu\text{m}$ ; trophozoite, 8 to 12  $\mu\text{m}$ ), vesicular nucleus, and large irregular karyosome. The cysts are often quadrinucleate.<sup>146,147</sup>

*Iodamoeba butschlii* is a nonpathogenic commensal organism. In the past it had been confused with the virulent *Naegleria* spp. It is less commonly encountered in the human gastrointestinal tract, occurring in 5% to 8% of the population in the tropics. It has a medium-sized trophozoite (9 to 20  $\mu\text{m}$ ) which is highly vacuolated with a large characteristic karyosome. The cysts of *I. butschlii* are uninucleate and contain a large, dense glycogen mass which stains with iodine and are thus identified as I cysts.<sup>146,147</sup>

*Blastocystis hominis* is an anaerobic protozoan that commonly inhabits the gastrointestinal tract of humans, where it resides in the cecum and large bowel.<sup>149–161</sup> Although it has a worldwide distribution (including infection in animals such as pigs, monkeys, rodents, and poultry), this protozoan is more commonly found in the tropics. The mode of transmission is unclear but, because of the association with unsanitary conditions, is believed to be oral-fecal spread. Prevalence rates are variable, but up to 52% of samples from homosexual males have evidence of infection with this organism in selected regions. The morphologic characteristics of *B. hominis* are its variable size (5 to 40  $\mu\text{m}$ ), lack of cell wall, and four morphologic forms: vacuolated, ameba-like, granular, and the recently described cyst stage. At present it is unclear whether the cyst form represents the infective form of the organism. Stool samples of persons infected with this organism typically reveal the vacuolated form, which is characterized by a large membrane-bound central body.

The pathogenicity of this organism is poorly understood, but in the last two decades there have been more frequent reports of infection with *B. hominis*. Infected persons may have gastrointestinal symptoms of diarrhea, abdominal pain, nausea, and vomiting, and systemic symptoms of anorexia and malaise. Reports of infection in immunocompetent and immunocompromised hosts are present in the literature. There is a paucity of diagnostic laboratory data (other than the identification of the vacuolated form of the parasite in stool samples stained with iron hematoxylin or trichrome stain) since stool studies typically lack fecal leukocytes, and endoscopic, histopathologic, and radiologic evaluations are

	Human Pathogen	Estimated Frequency	Trophozoite (usual size mm [range])	Cyst (usual size in mm)	Characteristic Features
<i>Entamoeba histolytica</i>	+	1%–10%	 10–20 (10–60)	 5–20	Central punctate karyosome, erythrophagocytosis
<i>E. coli</i>	–	3%–20%	 15–25 (10–50)	 10–30	Larger, to 8 nuclei splinterlike chromatoid bodies
<i>E. hartmanni</i>	–	?	 < 10	 4–10	“Small race”
<i>E. gingivalis</i>	–	10%–90% (mouth)	 15 (3–35)	None	Oral trophozoite only
<i>E. polecki</i>	±	Rare	 16–18	 12–14	Uninucleate cyst with large karyosome
<i>Endolimax nana</i>	–	10%–33%	 8–12	 6–10	Vesiculate nucleus
<i>Iodamoeba butschlii</i>	–	5%–8%	 9–20	 6–15	“I” cyst
<i>Dientamoeba fragilis</i>	+	4%–10%	 4–12	None	Binucleate trophs with connecting thread

**FIGURE 86-11** Amebae that infect the human gastrointestinal tract. (From Ravdin JI, Guerrant RL: Current problems in diagnosis and treatment of amebic infections. *Curr Clin Top Infect Dis* 7:82–111, 1986.)

usually normal. The organism has been shown to have in vitro sensitivity to a variety of agents, including emetine, metronidazole, furazolidone, co-trimoxazole, quinacrine, and pentamidine, and there are some in vivo data to support sensitivity of *B. hominis* to iodoquinol and co-trimoxazole. At present, the pathogenic potential of this protozoan parasite is unclear, its pathogenicity is poorly understood, and its role in causing human disease remains to be more clearly defined. Routine antimicrobial therapy against this organism is therefore not warranted.

*Dientamoeba fragilis*, once classified as an ameba, is now considered in the flagellate group and is discussed in Chapter 87.

# Intestinal Flagellate and Ciliate Infections

DAVID R. HILL  
THEODORE E. NASH

## INTRODUCTION

The most important of the many flagellates that inhabit the large and small bowel of man is *Giardia lamblia*; *Giardia* may be the most common pathogenic parasitic infection in humans. In developed countries, it is a frequent cause of endemic and epidemic diarrhea and in many developing regions of the world, where effective sanitation measures are lacking, infection is nearly universal by 2 to 3 years of age.

Of the other flagellates, only *Dientamoeba fragilis* is capable of causing enteric symptoms. *Chilomastix mesnili*, while not uncommonly seen in stool specimens, is a nonpathogen, as is *Pentatrichomonas hominis* (formerly known as *Trichomonas hominis*), and the rarely seen *Enteromonas hominis* and *Retortamonas intestinalis*. The only ciliate of man and the largest protozoan is *Balantidium coli*, a rare cause of diarrhea and dysentery, primarily in the tropics.

## ■ *Giardia lamblia*

### AGENT

*Giardia lamblia* (also known as *Giardia duodenalis* or *Giardia intestinalis*) is a flagellate protozoan that inhabits the small intestine of humans and other mammals. The genus *Giardia* belongs to the category of intestinal flagellates in the division Protozoa.<sup>1</sup> Analysis of the 16S small ribosomal RNA (rRNA) subunit as well as analysis of other essential proteins indicates *Giardia* is among the most primitive eukaryotes.<sup>2-4</sup> The trophozoite form lacks a definable Golgi apparatus, classical mitochondria, and peroxisomes, organelles that are found in higher eukaryotes.<sup>5,6</sup> It is likely that Antony van Leeuwenhoek described the organism in his own stool in the 17th century, but Vilem Lambl is credited with describing the trophozoite in humans in 1859 and Grassi discovered the cyst form in 1879.<sup>7</sup>

*Giardia* has only two morphologic forms, the trophozoite and the cyst (Fig. 87-1). The former resides in the small intestine and is responsible for disease manifestations and the latter is the infectious, environmentally resistant form responsible

#### Trophozoite

- 5–15  $\mu\text{m}$   $\times$  9–21  $\mu\text{m}$
- teardrop-shaped
- two nuclei
- four pairs of flagella
- claw-shaped median bodies
- ventral disk
- tumbling or swimming motion with synchronous beating of posterior flagella

#### Cyst

- 6–10  $\mu\text{m}$   $\times$  8–12  $\mu\text{m}$
- oval, smooth-walled
- one or two intracystic trophozoites with identifiable nuclei with central karyosomes
- prominent transverse claw-shaped median bodies and longitudinal axostyle

**FIGURE 87-1** Schematic drawing of *Giardia lamblia* trophozoite (top) and cyst (bottom), and their key identification points.

for transmission. The *Giardia* that infects humans is morphologically indistinguishable from that found in a large variety of mammals. The trophozoite is 9 to 21  $\mu\text{m}$  long, 5 to 15  $\mu\text{m}$  wide, and 2 to 4  $\mu\text{m}$  thick. When viewed from above, its shape resembles a pear or teardrop (Fig. 87-2). *Giardia* is bilaterally symmetrical, has two equal-sized nuclei that contain complete copies of the genome with a ploidy of four,<sup>8,9</sup> four pairs of flagella, one of which is recurrent, and possesses a ventral sucking disk which is used for adherence. Two claw-shaped median bodies consisting of microtubules conspicuously cross the middle of the parasite. These are typical of *G. lamblia* and contrast with the round median bodies in *G. muris*, a species found in some rodents.<sup>10</sup>

Despite the morphologic similarities among *Giardia* organisms that infect humans, analyses using a variety of complementary methodologies including isoenzyme analysis, rDNA sequence, presence of unique variant-specific surface proteins, and differences in isoenzymes or specific protein sequences indicate that *Giardia* isolates from humans vary. The human isolates fall into two major groupings that differ genetically and biologically.<sup>6,11-21</sup> In attempting to categorize them, there is no agreed-upon nomenclature. Groups 1/2 and Group 3, the initially described grouping,<sup>22</sup> are comparable to “Polish” and “Belgian” isolates and Assemblages A and B.<sup>6,20</sup> Assemblages have also been termed *genotypes*. Genetic differences between these two groups are so large that they are in reality different species although not officially recognized. Biological differences include variation in growth rates (T. Nash, unpublished observations), host specificity,<sup>23</sup> variant-specific surface protein repertoires,<sup>24</sup> and character of infection in animal models.<sup>25,26</sup> It is expected that there would be differences in virulence for humans between isolates of *Giardia*. While some studies indicate this,<sup>27-29</sup> others have shown clinical diversity with genetic similarity.<sup>30</sup> Therefore, there needs to be thorough analysis of isolates from all over the world with a careful correlation with clinical symptoms

**FIGURE 87-2** Scanning electron micrograph of the ventral surface of a *Giardia lamblia* trophozoite. The ventral adhesion disk and four pairs of flagella are seen. (Courtesy of D. Darwood, Rocky Mountain Laboratory, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD.)

before this can be resolved. In contrast, human host differences are known to contribute to the variability of clinical symptoms; patients who have common variable hypogammaglobulinemia are susceptible to severe and prolonged giardiasis.<sup>31</sup>

*Giardia* that are genetically indistinguishable from those infecting humans have been found in a wide range of animals including livestock, cats, and dogs.<sup>20,21</sup> In addition, *Giardia* originating from humans can experimentally infect a wide range of mammals. Although a reasonable interpretation of these data suggests cross-transmission between mammalian hosts and humans, with the exception of beavers,<sup>15</sup> no epidemics have implicated animals as a source of human infections. In other analyses, *Giardia* from cats, dogs, muskrats, domestic rats, and some hoofed animals such as sheep and cattle usually have distinct lineages with assignment to assemblages or genotypes with restricted enzootic potential.<sup>6,32–34</sup> Lastly, ongoing genetic analyses of *Giardia* found in specific animals support different species in rodents (*G. muris*), birds (*G. psittaci* and *G. ardeae*), and amphibians (*G. agilis*).<sup>6</sup>

Multiplication of trophozoites in the small intestine is by longitudinal binary fission with mirror image symmetry.<sup>35</sup> As trophozoites are swept down the intestine, they begin to form environmentally resistant, oval cysts (Fig. 87-3). These measure about 6 to 10  $\mu\text{m}$  long, have four nuclei, and the anlage of two trophozoites. Although bile salts trigger encystation in vitro,<sup>36</sup> more recent experiments indicate that encystation occurs through cholesterol depletion and micelle destruction in vitro,<sup>37</sup> a process that physiologically occurs in the intestine after absorption of lipids and bile salts in the lower small bowel.

*G. lamblia* is the only species that can be cultured in vitro.<sup>38</sup> Complex nondefined media are used and the organism grows best under anaerobic or microaerophilic conditions. It utilizes glucose as a major source of carbohydrate energy, producing ethanol, alanine, acetate, and carbon dioxide, and generating ATP in the process.<sup>6</sup> Another potential mechanism for ATP generation is the catabolism of arginine via the arginine dihydrolase pathway.<sup>39</sup> Exogenous cysteine is essential to survival. Unlike most eukaryotes, *G. lamblia* is unable to synthesize purines or pyrimidines and must salvage these from the intestine. Similar to many protozoans, it is unable to produce cholesterol but can synthesize farnesyl and geranylgeranyl to isoprenylate proteins.<sup>40</sup> Growth is inhibited in vitro by mevinolin<sup>40</sup> and this pathway may become a point of chemotherapeutic intervention.

Although *Giardia lamblia* is studied because it is an important pathogen, it is also of interest because it is one of the earliest branching eukaryotes. Defining its basic biological processes leads not only to an understanding of how primitive organisms like *Giardia* function and survive, but also when essential eukaryotic cellular mechanisms appeared and how they evolved.<sup>6</sup> The ability to culture and harvest large numbers of trophozoites axenically, induce encystation and excystation in vitro, and the availability of a nearly complete *Giardia* genome ([gmod.mbl.edu/perl/site/giardia?page=intro](http://gmod.mbl.edu/perl/site/giardia?page=intro))<sup>41</sup> has allowed comparison of *Giardia* proteins, biological processes, and pathways with those of higher eukaryotes. The recent availability of molecular biology-based methods to overexpress and/or epitope tag *Giardia* or exogenous proteins or to inhibit protein synthesis through antisense or RNAi-based mechanisms<sup>42,43</sup> permit experimental analysis of function in vivo.

*Giardia* is used as a model organism to study less complex developmental processes, vesicular transport, secretion, Golgi development, cyst wall development, transcription regulation, cytoskeleton organization, and other basic mechanisms present

**FIGURE 87-3** Scanning electron micrograph of a *Giardia lamblia* cyst (width 6.8  $\mu\text{m}$ ). (Courtesy of S. L. Erlandsen, Department of Cell Biology and Neuroanatomy, University of Minnesota School of Medicine, Minneapolis, MN.)

in earlier eukaryotes. The identification of residual organelles possessing remnants of mitochondrial proteins called mitosomes indicates that *Giardia* and similar eukaryotes are likely to have had mitochondria whose function has mostly been lost.<sup>44,45</sup> The possibility that *Giardia* had mitochondria also brings into question the evolutionary position of *Giardia*<sup>46</sup>; however, analysis of other essential proteins confirms its early lineage.<sup>2-4</sup> Other important discoveries with *Giardia* include an understanding of encystation and formation of the cyst wall as a model of an early and/or primitive developmental process as well as early secretory mechanisms,<sup>47-54</sup> and an understanding of novel transcription mechanisms.<sup>55,56</sup>

The trophozoite structure is rigid and it has its own complement of structural components, the most novel of which is a family of annexin-like proteins called giardins, some of which are immunodominant.<sup>57,58</sup> Vesicular transport does occur and is G protein dependent.<sup>59</sup> An NBD ceramide-staining structure, which is a marker for a Golgi apparatus in other eukaryotes, is not found in trophozoites but is seen in encysting organisms, suggesting that the Golgi apparatus is either formed or embellished during encystment.<sup>59</sup> The presence and nature of a sorting organelle is the subject of intense debate. *Giardia* possesses two equally functioning nuclei,<sup>60</sup> but it is not known how and if they cooperate and the manner of their communication (Fig. 87-4).

One of the most unusual features of *Giardia* is its surface, including the flagellae, which is covered by one of a family of unusual proteins (variant-specific surface proteins, VSPs) which undergo antigenic variation.<sup>24</sup> These change spontaneously at high rates during in vitro growth. The molecular weight of VSPs vary to a large degree and some of them have repetitive units.<sup>61,62</sup> These proteins are cysteine-rich (11% to 12% cysteine) occurring usually as CXXC motifs and have a conserved C terminal.<sup>24,63</sup> In addition, they have

zinc-finger motifs,<sup>24</sup> bind zinc,<sup>64,65</sup> and one purified VSP of two studied contained zinc and iron while another showed no zinc.<sup>64,66</sup> The surface location of zinc fingers is highly unusual in biology.

The biologic importance of VSPs is conjectural but their differential ability to resist digestion by intestinal proteases<sup>67</sup> suggests that individual VSPs have unique biologic properties. Although originally discovered as an in vitro phenomenon, antigenic variation occurs in vivo in humans<sup>68</sup> as well as in animal model infections.<sup>23</sup> During experimental human infection, a *Giardia* clone (GS/H7) expressing one VSP became replaced by a mixture of other VSPs between 2 and 3 weeks after inoculation.<sup>68</sup> This corresponds to the time when antibody responses to the original VSP are detected. However, whether or not antigenic variation allows immunologic escape, causing chronic infections, is unknown.<sup>24</sup> Under experimental conditions in animals with no adaptive immune system, certain VSPs are expressed preferentially.<sup>69</sup> Structural similarities and particular motifs are common to VSPs, whereas other regions differ and impart unique biological characteristics that are favored by or selected against by a specific host, perhaps allowing *Giardia* to expand its host range. Therefore, the surface presence of a particular VSP appears to be the result of a combination of biological and immune selection from a repertoire of randomly expressed VSPs.

Despite these advances in understanding the biology of *Giardia*, there are important gaps in our knowledge: How does *Giardia* cause disease, what is the nature of immunity in giardiasis, what is the role of parasite antigenic variation in establishing infection and survival, and what is the true role of animals as a source of human infections?

## EPIDEMIOLOGY

*G. lamblia* is one of the most widely distributed protozoan parasites, found in all climates and countries. Because transmission of *Giardia* requires oral ingestion of the cyst form of the parasite, the level of sanitation inversely correlates with the distribution of infection. Thus, poor levels of sanitation, as may be found in many developing regions, lead to fecal contamination of water and foods, accounting for high levels of childhood infection, and posing a risk to international travelers. In resource-rich regions of the world, relative resistance of the *Giardia* cyst to routine water treatment measures may allow the parasite to escape inactivation and contribute to frequent waterborne outbreaks of giardiasis. The wide distribution of *Giardia* is a major reason why it remains the most frequently found parasite in the United States, found in 4% to 7% of stools submitted to laboratories<sup>70</sup> and leading to an overall rate in 2002 of 7.4 cases per 100,000, with the highest rate of 23.5 in Vermont.<sup>71</sup>

There are three major modes of transmission—waterborne, direct fecal-oral, and foodborne. Waterborne transmission of giardiasis was first described in the 1960s from the United States,<sup>72</sup> and since that time has been repeatedly documented.<sup>71,73-76</sup> In the United States, *Giardia* remains one of the most common causes of outbreaks of diarrhea from water intended for drinking. From 1985 to 2000, it accounted for 39% of all outbreaks in which a cause was determined and affected several thousand people.<sup>76</sup> A frequent scenario for waterborne outbreaks is the use of *Giardia*-contaminated

**FIGURE 87-4** Transmission electron micrograph of an encysting trophozoite of *Giardia lamblia*. Two nuclei are readily seen, as well as the axonemes (intracytoplasmic projections of the flagella). Encystment-specific vesicles (ESV) are seen lining the dorsal surface. These contain cyst wall antigens. (Courtesy of B. Bowers, Laboratory of Cell Biology, National Heart and Lung Institute, National Institutes of Health, Bethesda, MD.)

# Giardia lamblia

surface water that has not been subjected to flocculation, sedimentation, and filtration, as well as chlorination. In 64% of drinking water-associated outbreaks, unfiltered water was used. In a large survey of surface water supplies used for municipalities at 66 sites in the United States and Canada, 81% had *Giardia* cysts detected at a mean concentration of three cysts per liter prior to treatment,<sup>77</sup> and 17% had cysts after treatment.<sup>78</sup> Although the concentration of parasites had fallen and the species of *Giardia* and cyst viability were not determined, it emphasizes the ubiquitous presence of *Giardia*. Other waterborne outbreaks have occurred because of direct fecal contamination of the water supply when underground pipes carrying sewage and purified water mixed.<sup>72,79</sup>

Recreational water has also been associated with giardiasis.<sup>71,76,80</sup> Because of the relative resistance of *Giardia* to chlorination, swimming pool water can be a vehicle for transmission

particularly when there are fecal accidents or contaminated diapers in the pool.<sup>81</sup> Mountainous areas of the United States and Canada have been particularly prone to waterborne outbreaks. Although it is not clear why this is the case, it may be that these areas use surface water that may be contaminated with *Giardia*, and because the water is cold, it allows cyst survival. Survival of cysts in cold lake or river water has been shown for up to 56 days.<sup>82</sup>

Direct fecal-oral transmission as may occur in day-care centers, custodial institutions,<sup>83</sup> or with anal-oral sexual practices is the second most common mode of transmission. Day-care centers throughout the world have had high infection rates, ranging from 20% to 50%.<sup>84,85</sup> Current surveys in Western settings are lacking. While many of the infected children may be asymptomatic, it is not uncommon for them to transmit *Giardia* to family members and thus contribute to high endemic

rates of infection in a community, and even contribute to endemic rates in the United States.<sup>86–88</sup> A common scenario is for a mother of a young child in day care to present to a physician with complaints of diarrhea due to *G. lamblia*. Although her child is asymptomatic, when the stool is checked, it is positive. In sexually active gay men, older surveys have demonstrated prevalence rates as high as 20%.<sup>89,90</sup>

The third mode of transmission, food, is increasingly recognized. Given the ability of the cyst to survive outside the human host, it is surprising that foodborne outbreaks are not more frequently described. Outbreaks have occurred in restaurants, corporate offices, nursing homes, and churches. They have usually followed ingestion of foods that have not been cooked, such as salads or cold meats and fish.<sup>91–93</sup> Transmission may occur with as few as 10 to 25 cysts, so only low levels of contamination are necessary to establish infection.<sup>94</sup>

Giardiasis occurs year-round, but some epidemiologic surveys from the United States and Scotland suggest a peak incidence of giardiasis in the late summer and early fall.<sup>71,86,95</sup> This incidence may be due to increased recreational exposure to water or more frequent international travel during the summer months.<sup>96,97</sup> Acquisition of *Giardia* during international travel is increased with travel of longer than a month in duration and with travel to the Indian subcontinent.<sup>98,99</sup>

As has been discussed, genetically similar organisms are found in humans and a large number of mammals suggesting the potential for zoonotic transmission. However, with the exception of beavers, there are no epidemics documented from animal sources to humans. An outbreak of beaver-to-human transmission that was waterborne occurred in British Columbia.<sup>75</sup> *Giardia* was detected from the water supplies and from a beaver nesting in the implicated water. The human, water, and beaver isolates were identical. Despite this documented occurrence, many of the genotypes associated with animal infection (assemblages or genotypes C-G) have not been found in humans, therefore lowering their zoonotic potential.<sup>6,32,33,100</sup> Specifically, there is no definitive transmission from dogs or cats to humans, and screening of domestic animals is not warranted.<sup>34,101</sup>

*Giardia* is a near ubiquitous agent in developing regions. It is one of the earliest of the enteric parasites to infect infants and has prevalence rates of 10% to 30% in children less than 10 years old.<sup>102–108</sup> In these settings, nearly all children will become infected at some point during their childhood.

## **PATHOGENESIS AND IMMUNOLOGY**

A hallmark of infection and disease caused by *Giardia lamblia* is clinical variability. Infections can be abortive, transient, or chronic, while accompanying disease manifestations can range from minor or none to fulminant diarrhea, severe malabsorption, and life-threatening malnutrition. Although poorly defined, both parasite and host factors are important in determining the control and susceptibility to infection and disease.

Infection follows the ingestion of as few as 10 to 25 cysts.<sup>94</sup> Excystation is initiated with exposure of cysts to stomach acid, intestinal proteases, and the stimulation of a parasite-derived protease.<sup>109,110</sup> Trophozoites that are released colonize the upper small bowel and can be present in such large numbers that they adhere to and cover a large portion of the

absorptive surfaces. They may adhere via the ventral disk or possibly via specific receptor ligands.<sup>111</sup> It seems important that parasites are able to adhere to gut mucosa. Gerbils given a high-fiber diet had reduced rates of infection, possibly because of trapping and clearance of trophozoites in the mucous blanket,<sup>112</sup> and humans with asymptomatic giardiasis had decreased parasite excretion following ingestion of wheat germ agglutinin.<sup>113</sup>

The large number of trophozoites present in the bowel suggests a direct effect of the trophozoite on intestinal function. Thus, damage to the brush border and its enzymatic system could be a possible mechanism for some of the changes documented in clinical infection, particularly disaccharidase deficiencies. In intestinal epithelial monolayers, *Giardia* isolates have caused disruption of tight junctions, increased permeability, and have induced apoptosis.<sup>114–116</sup> Another possibility to account for diarrhea in giardiasis is small bowel overgrowth. While this has been documented, it may be associative rather than causative, as the presence and degree of bacterial colonization does not correlate with the development of disease in human experimental infections.<sup>27</sup> Mucosal invasion is rare, and there has been no evidence of a classic enterotoxin.

Biopsies of the intestine show varying degrees of mucosal inflammation with crypt hypertrophy, villous blunting, and mucosal infiltration with mononuclear inflammatory cells.<sup>117–121</sup> This can rarely be as severe as an entirely flattened, spruelike gut. The inflammatory response may lead to diarrhea by increasing the number of secretory crypt cells.<sup>122</sup> Inflammation could also initiate a cytokine reaction leading to diarrhea, which may be similar to proposed mechanisms for other adherent or minimally invasive coccidian enteric protozoa.<sup>123</sup> The gut may become sensitized to parasite antigen itself.<sup>124</sup>

Many studies have been performed on the basic biology of the trophozoite in an attempt to understand whether there are virulence differences between isolates. By a number of in vitro biochemical and molecular measures, *Giardia* organisms from humans differ (see previous discussion). Biologic differences have been noted in both animal model infections<sup>26,125,126</sup> and experimental human infections.<sup>27</sup> For instance, infections with varying isolates differed in their duration, level of cyst excretion, and ability to induce homologous or heterologous immunity. In human experimental infections, only one of two isolates was able to infect volunteers, although both originated from symptomatic donors.<sup>68</sup> Although correlations have been made between certain genotypes or assemblages and clinical disease,<sup>28,29,127,128</sup> it is premature to associate one particular isolate or genotype with increased potential to cause disease<sup>30</sup> until extensive controlled studies have been carried out with isolates from many regions of the world.

In part, the response of the host to *Giardia* determines the course of infection and whether there will be disease. Knowledge of the role of the immune response comes primarily from animal models of *G. lamblia* in gerbils and of *G. muris* or *G. lamblia* in mice. Relatively little data are derived directly from humans. In animals, an immune response occurs that is characterized by both the ability to self-cure and to resist rechallenge.<sup>129,130</sup> However, this response is both host- and parasite-dependent, and some animals are less capable of mounting an effective immune response.

In humans, the data are variable. Eighty-four percent of experimentally infected persons self-cured on average 18 days following inoculation while the remainder became chronically infected.<sup>94</sup> Although the evidence is indirect, epidemiologic studies in human populations suggest some acquired immunity by demonstrating decreased prevalence of infection in endemically exposed persons compared with those newly exposed.<sup>72,131,132</sup> In developing regions, there is increased prevalence in the young compared with adults.<sup>102,133</sup> However, in highly endemic populations, reinfections are common if not universal in the young,<sup>107</sup> and relatively high prevalence rates continue even in older populations.

The development of an immune response to *Giardia* involves both humoral and cellular mechanisms. Humans and animals produce systemic immunoglobulin G (IgG), IgM, and IgA,<sup>27,102,120,133–140</sup> including cytotoxic antibodies.<sup>125,141–143</sup> There is an important intestinal IgA response to acute infection.<sup>68,144,145</sup> Indirect evidence suggests a role of IgA in control of experimental infections; mouse pups are resistant to infection with *G. muris* when nursed on immune dams,<sup>146</sup> and infection is prolonged in anti- $\mu$  treated mice.<sup>147</sup> IgA-deficient mice fail to clear infection with *G. lamblia*; however, they controlled infection better than B-cell knock-out mice, suggesting B-cell dependent, IgA-independent anti-*Giardia* defenses.<sup>148</sup> However, conflicting data from another study of *G. lamblia* infection in B-cell knock-out mice<sup>149</sup> leads to the possibility that responses are dependent on the species of *Giardia* employed, model used, and stage of infection evaluated. A possible mechanism by which intestinal antibodies could prevent or help to control infection is by interfering with an important adherence step and preventing adequate colonization by *Giardia*. The production of cytotoxic intestinal IgA antibodies is plausible but as yet unproved.

Cellular immune responses are essential. Athymic, nude mice infected with *G. muris* are unable to self-cure,<sup>150,151</sup> but partially control the infection after the administration of immune spleen cells. This control may come at a cost, however, since following reconstitution the gut may develop inflammatory changes<sup>150</sup> that may be mediated through CD8+ cells.<sup>152</sup> Furthermore, elimination of CD4+ T cells in Peyer's patches with anti-CD4 antibodies prevents self-cure in *G. muris*-infected mice.<sup>153</sup> Both nude and anti-CD4-treated mice are unable to mount an intestinal IgA response,<sup>153</sup> suggesting that T cells are essential to the production of specific intestinal IgA. Interleukin (IL)-6-deficient mice have difficulties in the early control of *G. lamblia* infection,<sup>154,155</sup> as do mast cell-deficient mice.<sup>156</sup> It is possible this effect relates to the role IL-6 has in stimulating T helper cell-induced clonal expression of IgA-producing B cells and plasma cells.

Specific proliferative responses are found in the Peyer's patches and mesenteric lymph nodes of infected animals,<sup>157,158</sup> as well as in peripheral mononuclear cells from humans.<sup>159</sup> Macrophages and neutrophils can phagocytose *Giardia*.<sup>160–163</sup> Macrophages could help to process *Giardia* antigen for the development of an immune response and also could release inflammatory mediators. The role of neutrophils is undefined and natural killer cells are not essential.<sup>164</sup>

Patients with common variable immunodeficiency have severe and prolonged infection with *Giardia*.<sup>31,165,166</sup> This may be secondary to their failure to produce antibody, but is also likely related to recent findings that this immunodeficiency can be primarily a cellular-based abnormality.<sup>167,168</sup> Patients with

X-linked agammaglobulinemia are also at increased risk.<sup>169</sup> Acquired immunodeficiency syndrome (AIDS) patients with severe cellular immunodeficiency may have giardiasis that is refractory to treatment.<sup>170</sup> Finally, local intestinal conditions including motility and microflora, and nonimmune defenses such as nitric oxide, may each play a role in whether or not *Giardia* can establish infection.<sup>171,172</sup>

## CLINICAL MANIFESTATIONS

Clinical giardiasis is varied and ranges from asymptomatic passage of cysts to chronic diarrhea, malabsorption, and weight loss. Most symptomatic patients, however, experience a fairly characteristic syndrome of diarrhea with foul-smelling stools and gas, bloating, and abdominal cramps (Table 87-1). Following ingestion of the cyst form, there is an incubation period of approximately 1 to 2 weeks before the onset of symptoms. The incubation period may be shorter than the prepatent period (the time from ingestion of cysts to excretion of cysts in the stool), which emphasizes the importance of not eliminating giardiasis as a diagnostic possibility if a single stool specimen is negative at the onset of symptoms.<sup>173</sup> It can be estimated that the percentage of patients naturally infected who will develop symptoms is about 50%, 15% or more will pass cysts asymptotically, and the remainder will show no trace of infection.

In addition to abdominal complaints in persons with symptomatic giardiasis, there is frequent malaise and anorexia. Indeed, one of the most helpful distinguishing features of giardiasis is weight loss, which occurs in over 50% of patients and averages 10 pounds. It is not clear if this weight loss is secondary to the absorptive defects seen in some patients or to the more frequent nausea and anorexia. Vomiting occurs in about one-fourth of patients and low-grade fever is uncommon. Traditional signs of inflammatory diarrhea such as tenesmus and gross blood in the stool do not occur. There has been a suggested association of

**Table 87-1** Symptoms of Giardiasis

Symptom	Percentage (Range)
Diarrhea	90 (64–100)
Malaise	86 (72–97)
Flatulence	75 (35–97)
Foul-smelling, greasy stools	75 (57–87)
Abdominal cramps	71 (44–85)
Bloating	71 (42–97)
Nausea	69 (59–79)
Anorexia	66 (41–82)
Weight loss	66 (56–76)
Vomiting	23 (11–36)
Fever	15 (0–24)
Constipation	13 (0–26)
Urticaria	10 (5–14)

Data from Moore GT, Cross WM, McGuire D, et al: Epidemic giardiasis at a ski resort. *N Engl J Med* 281:402–407, 1969; Dykes AC, Juranek DD, Lorenz RA, et al: Municipal waterborne giardiasis: An epidemiologic investigation. Beavers implicated as a possible reservoir. *Ann Intern Med* 92:165–170, 1980; Shaw PK, Brodsky RE, Lyman DO, et al: A communitywide outbreak of giardiasis with evidence of transmission by a municipal water supply. *Ann Intern Med* 87:426–432, 1977; Mintz ED, Hudson-Wragg M, Mshar P, et al: Foodborne giardiasis in a corporate office setting. *J Infect Dis* 167:250–253, 1993; and reviewed in Hill DR: Giardiasis: Issues in management and treatment. *Infect Dis Clin North Am* 7:503–525, 1993.

giardiasis with urticaria,<sup>174,175</sup> Whipple disease,<sup>176</sup> and a reactive arthritis.<sup>177</sup> Although *Giardia* is generally confined to the intestine, it has been found in the stomach almost always in association with atrophic gastritis and occasionally with *Helicobacter pylori*.<sup>178,179</sup>

Another helpful distinguishing feature is the duration of symptoms; the course of giardiasis is frequently prolonged. In the first published study of waterborne giardiasis, illness of 10 days or more was significantly associated with infection with *Giardia*.<sup>72</sup> While many patients will eventually resolve infection without treatment, others will go on to a syndrome of chronic diarrhea. This may alternate with constipation or normal bowel patterns; just as the patient prepares to present to the physician with diarrhea, he or she feels better, but then relapses in several days. This pattern may continue until the patient seeks medical care or the disease resolves.

While most patients with giardiasis have a fairly benign course, reports from the United States and Scotland define the range of potentially severe giardiasis.<sup>180,181</sup> In the U.S. survey, hospital discharges with a diagnosis of giardiasis were reviewed. It was found that from 1979 to 1988 there were approximately 4600 persons admitted annually for giardiasis with hospital admission rates (2 per 100,000 persons) similar to those for shigellosis. Persons most frequently affected were children under the age of 5 years and women of childbearing age. Volume depletion was the most common reason for admission, and 19% of children less than 5 years old had failure to thrive. Hypokalemia has also been associated with severe infection.<sup>182</sup>

Malabsorption of fat, vitamins A and B<sub>12</sub>, protein, and D-xylose has been documented in chronic infection.<sup>183–186</sup> Children who have been evaluated for failure to thrive have also been found to have giardiasis. In some cases, there is a correlation between symptoms, severity of malabsorption, and small bowel histopathologic changes, that is, inflammatory changes with villous flattening and crypt hypertrophy.<sup>118,120</sup> However, it is clear that some patients may have severe diarrhea without the corresponding pathologic changes, emphasizing the multiple potential mechanisms for the production of diarrhea in giardiasis. Lactose is the most common of the disaccharides to be affected and patients who resolve infection may be lactose-intolerant for several weeks. This should be investigated in patients who “relapse” with diarrhea after treatment, before another course of therapy is empirically given.

Asymptomatic infection is most commonly seen in children. This has been best documented in day-care settings where more than 20% of children will be infected, but fewer will actually be symptomatic. In these settings, cyst passage has been documented for 6 months or more.<sup>187,188</sup> While children are often asymptomatic, they may introduce *Giardia* to both day-care staff and family members.<sup>86,88</sup> In contrast, series have documented the association of giardiasis with malabsorption, failure to thrive, and catch-up growth when *Giardia* is eliminated.<sup>119,180,186,189</sup>

In developing regions where children may start from a point of poor underlying nutritional status, there is ample evidence for the deleterious effect of *Giardia* upon childhood nutrition and development. Reanalysis of the classic study of diarrhea in Guatemalan children by Mata,<sup>185</sup> as well as other studies, indicates a role for *Giardia* in chronic diarrhea (lasting 2 to 6 weeks) and malnutrition.<sup>102–104,190</sup> Recent work has shown that infection with *Giardia* is associated with stunted growth in children from Ecuador<sup>191</sup> and Turkey,<sup>192</sup> increased intestinal permeability in children in Nepal,<sup>193</sup> low weight-for-age and

height-for-age in children in Brazil,<sup>194</sup> and decreased cognitive function in children from Peru.<sup>108</sup> Catch-up growth in children treated for *Giardia* has also been documented.<sup>195</sup>

Therefore, *Giardia* clearly is capable of causing a chronic diarrheal syndrome in children that can be associated with malabsorption and which, in some settings, may contribute to retarded growth and nutritional deficiency. However, many children will be asymptomatically infected or coinfecting with other pathogens, necessitating individual assessment of the clinical setting.

## DIAGNOSIS

Because of its wide range of symptoms, giardiasis should be considered in many patients who present with diarrhea, particularly when diarrhea is prolonged and associated with weight loss. Each patient should be asked about epidemiologic risk factors of drinking water source, overseas travel, wilderness camping, day care, and sexual practices. These inquiries are especially important because the incubation period may be prolonged, and a patient may have returned from a place of exposure well before the onset of symptoms and, therefore, not associate the exposure.<sup>98,196</sup> Other diarrheal syndromes caused by viruses, noninvasive bacteria, parasites, and tropical sprue should be considered in the differential diagnosis. Similar syndromes, though generally more severe, are those produced by *Cryptosporidium parvum*, *Cyclospora cayetanensis*, and *Isospora belli*.<sup>123,197,198</sup> Since the epidemiology of *C. parvum* and *Cyclospora* are similar to that of *Giardia* and the clinical presentation and risk factors may overlap, they will need to be distinguished by stool examination.

Until recent years, the gold standard for the diagnosis of giardiasis was a stool examination for ova and parasites (O&P).<sup>199,200</sup> Now rapid detection of *Giardia* antigen using immunofluorescence, enzyme-linked immunosorbent assay (ELISA), and nonenzymatic assays has been employed by most commercial laboratories because of ease of use and high sensitivity and specificity. In the O&P exam, a stool is typically divided into three portions with one examined fresh, one placed in polyvinyl alcohol (PVA), and the third in 10% buffered formalin. The fresh stool can be examined under a saline wet mount or with the addition of iodine that becomes concentrated in the cysts of *Giardia*. A loose stool might yield motile trophozoites; a semi-formed or formed stool is more likely to contain only cysts. Preserved specimens can be permanently stained, usually with trichrome or iron hematoxylin and examined thoroughly. Finally, the stool can be concentrated by formalin-ether or zinc flotation techniques. Using an O&P exam, *Giardia* should be detected 50% to 70% of the time following one stool and as often as 90% following three stools.<sup>201</sup>

Commercial assays that detect *Giardia* antigen are more sensitive than the standard O&P. These assays are clearly an advance; however, they should not be done to the exclusion of an O&P in cases when other parasites are in the differential diagnosis. Some of the best situations in which to use antigen detection assays are in screening a population for *Giardia*, such as in an outbreak setting and children in day care, or for a test of cure. Assays that detect soluble antigen should be carefully interpreted in light of the clinical scenario, as they could be positive after a patient has stopped excreting intact, viable organisms.

Antigen detection generally utilizes polyclonal or monoclonal antibodies directed against cyst or trophozoite antigens.<sup>202,203</sup>

They are rapid to perform, less observer dependent than stool O&Ps, and are highly sensitive and specific. Two widely used commercial assays in the United States are the ProSpecT microplate EZ (EIA; Remel, Lenexa, KS) and the Merifluor DFA (Meridian Bioscience, Cincinnati, OH). The ProSpecT assay uses an ELISA to detect a cyst wall protein of *Giardia*<sup>204</sup> and has a sensitivity of 91% to 98% and a specificity of nearly 100%.<sup>205,206</sup> When compared directly with stool O&P, it consistently detects more positive stools. As with a stool O&P, there is increased sensitivity with three stool examinations.<sup>207</sup> The Merifluor immunofluorescence assay is a combination test using a monoclonal antibody to detect *Giardia* and a separate monoclonal antibody to detect *Cryptosporidium*.<sup>206,208,209</sup> This assay has similar sensitivity and specificity to that of the ELISA. A nonenzymatic, solid-phase assay has also been introduced, called ImmunoCard STAT! *Cryptosporidium/Giardia* Rapid Assay (Meridian Bioscience, Cincinnati, OH).<sup>210</sup> With low levels of parasites in the stool ( $\leq 100$  cysts/10  $\mu$ L), the non-immunofluorescence assays had more false negatives.<sup>208,210</sup> The use of genomic probes has been primarily used to detect *Giardia* cysts in water,<sup>211</sup> although efforts are being made to adapt it to the clinical laboratory.<sup>212,213</sup>

When a careful history has been taken and a stool properly tested for *Giardia*, most cases of giardiasis should be diagnosed. This lessens the need for duodenal sampling. Early studies indicated that duodenal aspiration, biopsy, or the string test had higher yields than the standard O&P.<sup>214–217</sup> While the new diagnostic tests have not been measured against duodenal sampling, it is likely that they are as sensitive and they are certainly less invasive and expensive for the patient. Duodenal aspirates or biopsies, however, should be used in patients for whom the diagnosis of giardiasis cannot be made by stool

examinations, when there is a broad differential diagnosis, or when it is important to examine the histology of the small bowel. Small bowel biopsy may be particularly helpful in patients with human immunodeficiency virus (HIV) infection or AIDS, common variable immunodeficiency, or suspected sprue.

Serology has been reserved for seroepidemiologic studies and research settings.<sup>102,135,136</sup> It has not been developed for commercial use in diagnostic laboratories because of the ease and sensitivity of stool assays and because the serologic response to a noninvasive pathogen may be less reliable for individual diagnosis. Culture of human isolates has been accomplished, but is generally limited to research laboratories.<sup>38</sup> Duodenal isolates may be directly cultured and cysts obtained from stool may be excysted in vitro or in vivo in mice or gerbils and then cultured.<sup>218,219</sup>

Radiography is generally not specific and of little use in the diagnosis of giardiasis, but may reveal other lesions when there is a broader differential diagnosis. Findings on upper gastrointestinal studies have included an increased transit time and irregular thickening of the small bowel folds. Nodular lymphoid hyperplasia has been seen in patients with common variable immunodeficiency. Peripheral white blood cell counts are normal; eosinophilia is not seen. Stools should not contain inflammatory cells.

## TREATMENT AND PROGNOSIS

Symptomatic patients with giardiasis should be treated (Table 87-2). Because routine culture and sensitivity testing of *Giardia* isolates is not available and in vitro results do not always correlate with the clinical picture, treatment protocols have been based on clinical experience.<sup>220,221</sup> Therapeutic classes

**Table 87-2 Treatment of *Giardia lamblia*, *Balantidium coli*, and *Dientamoeba fragilis***

Drug	Dosage	
	Adult	Child
<b>Giardiasis</b>		
Tinidazole	2 g $\times$ 1 dose	50 mg/kg $\times$ 1 dose (max. 2 g)
Metronidazole*	250 mg tid $\times$ 5–7 days	5 mg/kg tid $\times$ 5–7 days
Nitazoxanide	500 mg bid $\times$ 3 days ( $\geq 12$ years)	100 mg q12h $\times$ 3 d (age 12–47 months) 200 mg q12h $\times$ 3 d (age 4–11 years)
<b>Alternatives</b>		
Furazolidone	100 mg qid $\times$ 7–10 days	2 mg/kg qid $\times$ 10 days
Quinacrine†	100 mg tid $\times$ 5–7 days	2 mg/kg tid $\times$ 7 days
Paromomycin*	500 mg tid $\times$ 5–10 days	30 mg/kg/day in 3 doses $\times$ 5–10 days
Albendazole*	400 mg qd $\times$ 5 d	15 mg/kg/day $\times$ 5–7 days (max. 400 mg)
<b>Balantidiasis</b>		
Tetracycline**	500 mg qid $\times$ 10 days	10 mg/kg qid $\times$ 10 days (max. 2 g/day)
Iodoquinol*	650 mg tid $\times$ 20 days	40 mg/kg/day in 3 doses $\times$ 20 days (max. 2 g/d)
Metronidazole*	500 mg bid $\times$ 5 days	25–35 mg/kg/day in 3 doses $\times$ 5 days
<b><i>Dientamoeba fragilis</i></b>		
Iodoquinol*	650 mg tid $\times$ 20 days	40 mg/kg/day in 3 doses $\times$ 20 days (max. 2 g/d)
Tetracycline**	500 mg qd $\times$ 10 days	10 mg/kg qid $\times$ 10 days (max. 2 g/day)
Paromomycin*	500 mg tid $\times$ 7–10 days	25–30 mg/kg/day in 3 doses $\times$ 7–10 days

\*Not a U.S. Food and Drug Administration–approved indication.

†No longer produced in the United States. May be obtained from certain compounding pharmacies such as Panorama Pharmacy, Panorama City, CA (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-6816).

\*\*Not recommended for use in children less than 8 years of age.

that have demonstrated both in vitro and clinical efficacy include the nitroimidazoles, nitrofurans, benzimidazoles, and a newly released agent, nitazoxanide.<sup>220,222</sup> The nitroimidazoles are the standard for treatment.

In 2003 and 2004, two agents were released in the United States for treatment of giardiasis: tinidazole (Tindamax, Presutti Labs) and nitazoxanide (Alinia, Romark).<sup>222,223</sup> These agents increase treatment options and should allow most patients with giardiasis to be successfully treated. Until the release of tinidazole in 2004, metronidazole (Flagyl) had become the drug of choice following the discontinuation of quinacrine production in the United States in 1992. Tinidazole is now the agent of choice. It has more than 3 decades of experience in the treatment of giardiasis (as well as amoebiasis and trichomoniasis) outside of the United States. From these studies, it is considered to be the most effective agent against *Giardia* and, because it has a longer half-life than metronidazole, can be given as a single dose (2 g in adults).<sup>220,224–226</sup>

Although metronidazole had never been approved by the U.S. Food and Drug Administration for use in giardiasis, it has proved both safe and effective from extensive clinical experience.<sup>220</sup> Most patients should receive metronidazole in divided doses over 5 to 7 days. Although short-course (1 or 2 days), high-dose regimens have been used, they are less effective than longer courses and may be poorly tolerated. Side effects from tinidazole and metronidazole are similar, but tinidazole may be better tolerated.<sup>227,228</sup> These side effects include headache, vertigo, nausea, and a metallic taste (Table 87-3). Rarely, central nervous system toxicity and a reversible neutropenia occur. The drugs should not be taken with alcohol because they may produce a disulfiram-like effect. There has been concern about potential carcinogenicity of metronidazole in children. Although the drug may be mutagenic in bacteria and carcinogenic in high doses when given to animals, these findings have never been documented in humans, and the drug has accepted use in children for the treatment of anaerobic infections and amoebiasis.<sup>229–231</sup> Similar concerns would apply to tinidazole. Ornidazole, a nitroimidazole not available in the United States, has excellent efficacy when given over several days or as a single dose.<sup>220,232</sup>

Nitazoxanide was released in the United States in 2003 for treatment of giardiasis and cryptosporidiosis in children, and then approved in 2004 for treatment of adults.<sup>222</sup> This drug is active against a wide variety of parasites and bacteria, including some helminths. Although there is limited experience of the drug in patients with giardiasis, it appears to be effective in 70% to 85% of cases when given over 3 days.<sup>233–237</sup> Its main side effect is gastrointestinal.

Furazolidone (Furozone, Roberts), a nitrofuran, has been used in children because a liquid preparation is available and the drug is generally well tolerated. However, tinidazole may be made into syrup and nitazoxanide comes in a liquid formulation. Furazolidone has an efficacy of 80% to 95% and needs to be given in four divided doses for 7 to 10 days.<sup>220,238,239</sup> Side effects may include gastrointestinal upset, brown discoloration of the urine, and mild hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient persons. Although this drug may be carcinogenic in rodents when given in high doses, this has never been established in humans and has received little attention compared with that given to metronidazole.<sup>240</sup>

The benzimidazoles, particularly mebendazole and albendazole, have been studied in giardiasis. Although mebendazole (Vermox, McNeil) demonstrated good activity in vitro, the results of clinical studies have been variable and generally disappointing.<sup>220</sup> Albendazole (Albenza, GlaxoSmithKline) is more effective than mebendazole and, when given in a single daily dose of 400 mg for 5 days, successfully treated 95% of infections in Bangladeshi children.<sup>241</sup> Several other clinical studies have confirmed its effectiveness, although not always at this high level.<sup>242–245</sup> It needs to be given for 5 days; shorter courses are less effective.<sup>241,246</sup> Because of albendazole's ability to kill other intestinal helminths, it is attractive when considering treatment of intestinal parasitism in resource-poor regions of the world, as is nitazoxanide.<sup>247</sup> Bacitracin zinc 120,000 units (USP) twice daily was effective in a trial in Tanzania, but this agent is not readily available for use and requires a 10-day course of therapy.<sup>248</sup>

Quinacrine is a highly effective agent, but it has not been produced in the United States since 1992. Clinical efficacy is greater than 90%.<sup>220,249</sup> If quinacrine can be obtained from

**Table 87-3 Treatment of Giardiasis—Efficacy and Adverse Events**

Drug	Efficacy	Adverse Events
Tinidazole	85%–98%	As for metronidazole
Metronidazole	80%–95%	Gastrointestinal, metallic taste, headache, disulfiram-like effect, rash; Rare: leukopenia, neuropathy, seizures ?mutagenic/carcinogenic
Nitazoxanide	70%–85%	Abdominal pain, diarrhea, vomiting, headache
Furazolidone	80%–95%	Gastrointestinal, allergic reaction, headache, disulfiram-like effect Do not take with tyramine- or tryptophan-containing food or drink, or with tricyclic antidepressants Rare: mild hemolysis in G6PD deficiency ?carcinogenic
Quinacrine	90%–95%	Gastrointestinal, headache, yellow discoloration Rare: toxic psychosis Should not be given to patients with psoriasis
Paromomycin	55%–90%	Gastrointestinal
Albendazole	85%–95%	Anorexia, constipation Rare: reversible neutropenia and elevated liver enzymes

G6PD, glucose-6-phosphate dehydrogenase.

alternative sources, it should be given for 5 to 7 days. It may not be as well tolerated as other agents, particularly in children,<sup>239</sup> with potential side effects of a bitter taste; nausea and vomiting; yellow discoloration of urine, skin, and sclerae; and a rare drug-induced psychosis.

Treatment of giardiasis in pregnancy has been controversial. If a woman has mild disease and is able to maintain both adequate hydration and nutrition, then treatment can be delayed until after delivery or at least until the mother has progressed beyond the first trimester. If treatment is required, the options usually considered are metronidazole or paromomycin. The safety of metronidazole has been extensively studied and information indicates that it is probably safe in the final two trimesters,<sup>220,250–252</sup> but it should be avoided in the first trimester.<sup>253</sup> Tinidazole is Pregnancy Category C and is contraindicated in the first trimester.<sup>254</sup> An alternative to nitroimidazoles is paromomycin, a nonabsorbable aminoglycoside. There is limited information on the treatment of *Giardia*; efficacy varies from 55% to 90% of cases.<sup>220,255–257</sup> It has the theoretical advantage of not being appreciably absorbed and therefore avoiding potential fetal toxicity.

Drug resistance can occur with *Giardia* and has been most completely studied with metronidazole. It appears that the mechanism of action of metronidazole in giardiasis is through covalent binding of activated drug to parasite DNA, resulting in trophozoite death.<sup>258</sup> The drug also inhibits parasite respiration.<sup>259</sup> Activation of metronidazole occurs following reduction of the nitro group by acceptance of electrons from parasite protein ferredoxins.<sup>260,261</sup> Resistance correlates with decreased parasite pyruvate:ferredoxin oxidoreductase.<sup>258,260</sup>

Patients who fail a course of treatment may do so because of drug resistance, host factors, or simply failure of a single course of treatment. For patients who fail treatment or infrequently relapse, repeat therapy with the same agent, using a drug of a different class, or combination therapy with metronidazole and quinacrine may be effective.<sup>170,262</sup> Nitazoxanide may also be effective in persons with resistant parasites.<sup>263</sup> Patients who clinically relapse should be documented to have giardiasis since many persons who have recovered have prolonged lactose intolerance that can mimic infection. Functional bowel disease has been another association with *Giardia* infection.<sup>264</sup> Repeated failures should be investigated for a potential immune defect such as common variable immunodeficiency.

Treatment of persons asymptomatically excreting *Giardia* cysts has been controversial, particularly when reinfection is likely to occur as in children in developing regions or in day-care settings.<sup>107,265,266</sup> Therefore, in each clinical setting one needs to balance the effect of *Giardia* on the host, the cost and tolerance of treatment, and the ability to obtain a sustained elimination of the parasite. If *Giardia* is contributing to nutritional abnormalities in children, a case can be made to treat. Because of the possibility of transmission in food, all food handlers should be treated.

## PREVENTION AND CONTROL

The prevention of giardiasis requires the provision of potable water and adequate sewage treatment for communities and personal hygiene for individuals. Because of the wide contamination of surface water with *Giardia* cysts, treatment

of water supplies needs to be adequate to remove or inactivate these relatively hardy cysts. Water should be treated by flocculation, sedimentation, filtration, and then chlorination. Most municipal water supplies use chlorine at levels of approximately 0.4 mg/L. This level of chlorination, when used alone, may not be sufficient to inactivate cysts, so it is important that the other measures are also in place.<sup>267</sup>

In order to purify water for personal use when camping or traveling overseas, it can be brought to a boil (or boiled for a minute if at high altitude), filtered using small-volume water filters (pore size of less than 1  $\mu\text{m}$ ), or halogenated with chlorine or iodine preparations.<sup>268</sup> Chlorine preparations may be more subject to temperature, pH, and turbidity than iodines, so some recommend iodine over chlorine.<sup>268–270</sup> When using halogens, it is important to increase contact time for cold water and increase the dose of the halogen for turbid water. All halogenation techniques may be inadequate for *Cryptosporidium* and therefore filtration or boiling is more reliable,<sup>271</sup> especially when traveling overseas where there is a higher likelihood of acquiring *Cryptosporidium* than from wilderness water in the United States.<sup>272</sup> The sensitivity of *Cyclospora* to halogens is likely to be similar to *Cryptosporidium*. When enteric viruses are a concern and a filter is being used, the water should also be halogenated since viruses will escape the filtration process.

Prevention of transmission in endemic foci such as day-care centers is a particular problem as it has been difficult to decrease transmission and lower prevalence rates.<sup>187</sup> In addition, it is possible that asymptomatic infection in some children who are otherwise well-nourished will have little deleterious effect on the child.<sup>188,273,274</sup> In one day-care study, a strict intervention policy with exclusion and treatment of both symptomatic and asymptomatic children did not result in better control, but incurred higher costs because of the need for parents to stay home with children.<sup>275</sup> The study may be flawed, however, because of the high incidence of giardiasis in the community and, therefore, the large number of children who came into day care with infection. Certainly symptomatic children, teachers, and family members should be treated. If strict hand washing, separation of diaper changing areas from play and food areas, and treatment of symptomatic children does not control the problem, then consideration can be given to treating all infected children.

Prospects for the control of giardiasis in developing regions are limited until there are both the financial resources and political and community will to provide for the proper disposal of sewage and the provision of potable water. Sanitary interventions that improve hygiene should be combined with screening and treatment of diarrheal disease, including that caused by *Giardia*. Breastfeeding has been associated with lower rates of infection in developing regions, particularly when maternal milk has contained antibody to *Giardia*.<sup>104,276–278</sup> Currently, there is no prospect for a vaccine against infection in humans.

## ■ *Balantidium coli*

*Balantidium coli* is the largest intestinal protozoan of man and the only ciliate (Fig. 87-5).<sup>279</sup> It is a rare cause of diarrhea and inflammatory colitis. The trophozoite ranges in size from 60  $\mu\text{m}$  to 70  $\mu\text{m}$  (it can be as long as 150–200  $\mu\text{m}$ ), is

**FIGURE 87-5** Schematic drawing of *Balantidium coli* trophozoite (top) and cyst (bottom), and their key identification points.

usually ovoid in shape, and has a large, kidney-shaped macronucleus with a small micronucleus often lying in its concavity (Fig. 87-6). Anteriorly it has a tunnel-shaped cytosome and posteriorly a small opening in the cell membrane called the cytopye. Within the cytoplasm, there are numerous vacuoles and occasional intracellular erythrocytes. It is covered by longitudinal rows of cilia, which help to propel the organism. The cyst form is also large, 40 to 60  $\mu\text{m}$ , round to oval, and smooth-walled. The characteristic nucleus may be visible.

Humans are an incidental host to this pathogen, which frequently inhabits the large bowel of many mammals. Pigs are likely to be one of the main sources of human infection, as they are commonly infected.<sup>280,281</sup> A cluster of cases of human infection in Papua New Guinea demonstrated close

**FIGURE 87-6** Trophozoite of *Balantidium coli*. The large, eccentric, kidney-shaped nucleus is readily seen. The surface is covered with short cilia. The arrow indicates the cytosome. (From Baskerville L, Ahmed Y, Ramchand S: *Balantidium colitis*. Report of a case. Dig Dis 15:727, 1970. Reproduced with permission of S. Karger AG, Basel.)

association of humans with pigs,<sup>282</sup> as did cases in a rural community in Venezuela.<sup>283</sup> A large outbreak of balantidiasis was reported from the Truk Islands in Micronesia, where it was postulated that the water supplies became contaminated with pig feces after a typhoon.<sup>284</sup> However, cases in Muslims from Iran did not have pig exposure, indicating that there are other sources of infection.<sup>285</sup> The parasite has been found in amphibians and insects.<sup>286</sup>

While symptomatic infection with *B. coli* has been reported from the Americas, Africa, and Latin America, it remains unusual. In the United States, it was found in less than 0.1% of stools and from only three states.<sup>70</sup> This low prevalence in the United States is similar to that found in other temperate climates.<sup>286,287</sup> Cases in captive, lowland gorillas and other primates have been described.<sup>288,289</sup>

Clinical infection ranges from asymptomatic, accounting for over 50% of cases, to chronic, intermittent diarrhea and weight loss, to acute dysentery in about 5% of cases.<sup>288,290</sup> Diarrhea is characterized by several loose stools per day, abdominal pain, and cramps, and may be associated with blood and mucus. Appendicitis, intestinal perforation with peritonitis and death, and disseminated infection to liver and lung have all been reported but are rare.<sup>290–295</sup> Most cases of severe extrapulmonary infection have occurred in immunocompromised hosts.<sup>296,297</sup>

In experimental infection, *B. coli* appears to cause disease by invasion of mucosa from the terminal ileum to rectum with subsequent inflammation.<sup>298</sup> These findings are borne out by sigmoidoscopic and pathologic specimens of human infection.<sup>286,290,299</sup> The penetration of the mucosa may be aided by the action of a hyaluronidase.<sup>300</sup> Most often ulcers are multiple and superficial, but they can progress to deep ulceration with perforation. The ulcers may resemble those formed by *Entamoeba histolytica*.

The diagnosis is made by demonstrating trophozoites in fresh stools or ulcer scrapings from the colon. While cysts may be found in the stool on O&P exam, it is more common to make the diagnosis by finding trophozoites.<sup>285,286,290</sup> *B. coli* can be grown on artificial media,<sup>38</sup> but this method is not readily available. Treatment is effective with tetracycline, iodoquinol, and metronidazole (see Table 87-2).<sup>221,282,286,301,302</sup>

## ■ *Dientamoeba fragilis*

*Dientamoeba fragilis* is an occasional intestinal protozoan of humans; its role in the causation of diarrhea has been controversial.<sup>279</sup> At its first description,<sup>303</sup> *D. fragilis* was classified as an ameba. However, immunologic and ultrastructural studies have placed it in the flagellate group, related to the *Histomonas* and *Trichomonas* genera.<sup>304–307</sup> Morphologically, it exists only in the trophozoite form (Fig. 87-7). It is 9 to 12  $\mu\text{m}$  in size, usually has two nuclei (in arrested telophase) with a granular appearance, and frequent intracytoplasmic vacuoles. Although categorized as a flagellate, it has no flagella and does not exhibit directed motility in wet microscopy.

*D. fragilis* is found throughout the world. In a survey of enteric parasites in the United States, it was identified in 0.5% of stools submitted; over 50% of those identified were from California.<sup>70</sup> In Canada, it was found in 4% of stools from over 40,000 people<sup>308</sup>; in Egypt, in 13% of submitted stools<sup>309</sup>; and

**Trophozoite**

- 7–12  $\mu\text{m}$
- rounded
- one or two (80%) nuclei with four to eight symmetrical chromatin granules
- intracellular vacuoles and bacteria
- best identified in permanent stains
- active pseudopods, but sluggish motility

**Cyst**

No cyst stage

**FIGURE 87-7** Schematic drawing of *Dientamoeba fragilis* trophozoite and its key identification points. *D. fragilis* has no cyst stage.

in Oman, 5% of stools.<sup>310</sup> Because the parasite only exists in the trophozoite form, it can be difficult to detect in stool, and thus may be missed by many laboratories unless appropriate techniques are used.<sup>311</sup> Thus, standard surveys may underestimate its true prevalence. In selected populations in the United States, the prevalence has been as high as 19% to 50%.<sup>312,313</sup> It is seen overseas, often in conjunction with other intestinal parasites, and was identified in 20% of stools of returned missionaries.<sup>314–316</sup>

Transmission of *D. fragilis* is presumed to be via the fecal-oral route. How it might survive stomach acid is not clear. Because of its association in some studies with *Enterobius vermicularis* (pinworm),<sup>308,317</sup> some investigators have proposed that the parasite is transmitted in the pinworm eggs.<sup>318–320</sup> This has never been formally proved.

The ability of *D. fragilis* to cause gastrointestinal symptoms has been debated through the years because the parasite is frequently seen both in conjunction with other intestinal protozoa and in asymptomatic individuals. Several studies that have surveyed patients with only *D. fragilis* in their stools have described symptoms of diarrhea, abdominal pain (frequently epigastric or lower quadrant), increased flatus, anorexia, fatigue, and malaise.<sup>308–310,317,321–326</sup> Abdominal symptoms may have been present for weeks.<sup>322,324,326</sup> A case report describes *D. fragilis* mimicking appendicitis.<sup>327</sup> While it appears to be confined to the large intestine, it has been detected in bile.<sup>315</sup> Reports of severe infection are rare.<sup>328</sup>

The diagnosis of *Dientamoeba* infection requires the proper handling of stools. Stools should be placed in a fixative, usually polyvinyl alcohol, and then permanently stained and examined.<sup>308,311</sup> A simple wet mount or iodine stain will miss many infections, and the parasite quickly disintegrates if mixed with water. Three stool examinations should increase the yield from approximately 70% to 90%.<sup>201</sup> Although the organism can be cultured, growth is not able to be sustained.<sup>38,315,329,330</sup> Detection by immunofluorescence and polymerase chain reaction (PCR) have been described but remain investigative.<sup>331,332</sup> An association has been the finding of peripheral eosinophilia,<sup>333</sup> but why this protozoan parasite should cause eosinophilia is not clear. Many of the cases of eosinophilia have been in patients in whom pinworm was also seen or in immigrant populations in whom other helminthic infections were not adequately ruled out.<sup>311,321,322</sup>

Successful treatment has been with metronidazole, secnidazole (a nitroimidazole not available in the United States),

**Trophozoite**

- 6–10  $\mu\text{m} \times 10\text{--}20 \mu\text{m}$
- pear shape, with posterior taper
- single anterior nucleus with small karyosome
- three anterior flagella
- spiral groove
- cytosome with curved "shepherd's crook" fibril
- irregular, jerking movement by anterior flagella

**Cyst**

- 6–10  $\mu\text{m}$
- unique lemon shape with anterior polar knob
- thick-walled
- single nucleus
- curved cytosomal fibril

**FIGURE 87-8** Schematic drawing of *Chilomastix mesnili* trophozoite (top) and cyst (bottom), and their key identification points.

iodoquinol, and tetracycline<sup>221,317,321,323,333,334</sup> (see Table 87-2). In vitro, paromomycin is also active.<sup>335</sup>

## Other Flagellates

The other flagellates of humans are considered to be non-pathogens or commensals.<sup>336,337</sup> When they are found in the stool, they are often seen in association with other organisms and are a marker of fecal-oral contamination.<sup>313,338</sup> Rare clinical cases, including extra-intestinal infections, have been associated with them when other pathogens have been ruled out.<sup>339–342</sup> In stool surveys from the United States, *Chilomastix mesnili* (Fig. 87-8) and *Pentatrichomonas hominis* (formerly known as *Trichomonas hominis*, and named because a fifth "independent" flagellum is often seen; Fig. 87-9) were found in fewer than 0.5% of specimens.<sup>70</sup> However, in missionaries

**Trophozoite**

- 5–8  $\mu\text{m} \times 10\text{--}15 \mu\text{m}$
- oval or pear shape
- single anterior nucleus
- four anterior flagella
- undulating membrane with posterior projecting flagellum
- unique costa, or thin rod at attachment of body to membrane
- central axostyle with sharply pointed posterior protrusion
- rapid, jerking movement with wavelike motion of undulating membrane

**Cyst**

No cyst stage

**FIGURE 87-9** Schematic drawing of *Pentatrichomonas hominis* trophozoite and its key identification points. *P. hominis* has no cyst stage.

**Trophozoite**

- 3–6  $\mu\text{m} \times 4\text{--}10 \mu\text{m}$
- oval or pear shape
- single anterior nucleus with prominent karyosome
- three anterior flagella
- one posterior-projecting flagellum
- no undulating membrane
- rapid, jerking motion

**Cyst**

- 6–8  $\mu\text{m}$
- oval shape
- one to four nuclei seen

**FIGURE 87-10** Schematic drawing of *Enteromonas hominis* trophozoite (top) and cyst (bottom), and their key identification points.

returning from the developing world, *C. mesnili* and *P. hominis* were seen in 3% and 2%, respectively,<sup>314</sup> and in a Native American population *C. mesnili* was identified in 20% of stools.<sup>312</sup> In stool O&P, the cyst of *C. mesnili* has a characteristic lemon-shaped cyst with an apical knob. *P. hominis*<sup>343</sup> has only a trophozoite stage. *Enteromonas hominis* (Fig. 87-10) and *Retortamonas intestinalis* (Fig. 87-11) are rare infections. *Trichomonas tenax* may be seen in the oral cavity; its role in causing periodontal disease is unclear.<sup>343</sup>

**Trophozoite**

- 3–4  $\mu\text{m} \times 4\text{--}10 \mu\text{m}$
- oval or pear shape
- single anterior nucleus with karyosome
- two anterior flagella
- cytosome anteriorly with fibril
- rapid, jerking motion

**Cyst**

- 3–5  $\mu\text{m} \times 4\text{--}7 \mu\text{m}$
- pear shape
- single nucleus
- two fibrils seen extending from nucleus to end of cyst, resembling a bird's beak

**FIGURE 87-11** Schematic drawing of *Retortamonas intestinalis* trophozoite (top) and cyst (bottom), and their key identification points.

# Cryptosporidiosis

OLUMA YOSEPH BUSHEN

ALDO A.M. LIMA

RICHARD L. GUERRANT

## INTRODUCTION

*Cryptosporidium*, like *Isospora*, *Cyclospora*, and *Sarcocystis*, are intestinal coccidia related to the apicomplexan protozoa infecting humans, including *Plasmodium* species causing malaria. Intestinal coccidia are characterized by the fecal excretion of oocysts, which are the product of a sexual cycle of reproduction in the epithelium of the small intestine.

The coccidian protozoa have long been identified as veterinary pathogens, but their recognition as causes of human diarrheal disease is relatively recent. Although a few sporadic human cases had been reported previously, it was the worldwide spread of human immunodeficiency virus (HIV) in the 1980s that brought these organisms to prominent medical attention, since they tend to produce severe, protracted diarrhea in patients with advanced acquired immunodeficiency syndrome (AIDS). With subsequent increased surveillance and impressive waterborne and occasional food-borne outbreaks, however, *Cryptosporidium* has been identified as a major cause of diarrhea in children, often with long-term developmental impairment, as well as in immunocompetent persons in many settings, especially in tropical, developing areas around the world. Its unique characteristics of chlorine resistance and dependence on cell-mediated immunity for resolution of infection may place it among the most problematic enteric pathogens of the new century.

## AGENT

### History

*Cryptosporidium* was first described in 1907, primarily as a cause of diarrhea in animal species. The first human cases of cryptosporidiosis were published in two reports in 1976, one in a 3-year-old child with enterocolitis<sup>1</sup> and the other in a 39-year-old patient on cyclophosphamide and prednisolone for severe bullous pemphigoid,<sup>2</sup> and only seven more cases were reported until the early 1980s, when it was recognized as a common and debilitating pathogen in patients with AIDS. Though the first recorded epidemic occurred in 1984,<sup>3</sup> the most memorable one occurred in Milwaukee, when an outbreak affected greater than 400,000 people, contributed to the deaths of more than 50 AIDS and chemotherapy patients, and resulted in the loss of more than \$96.2 million in lost

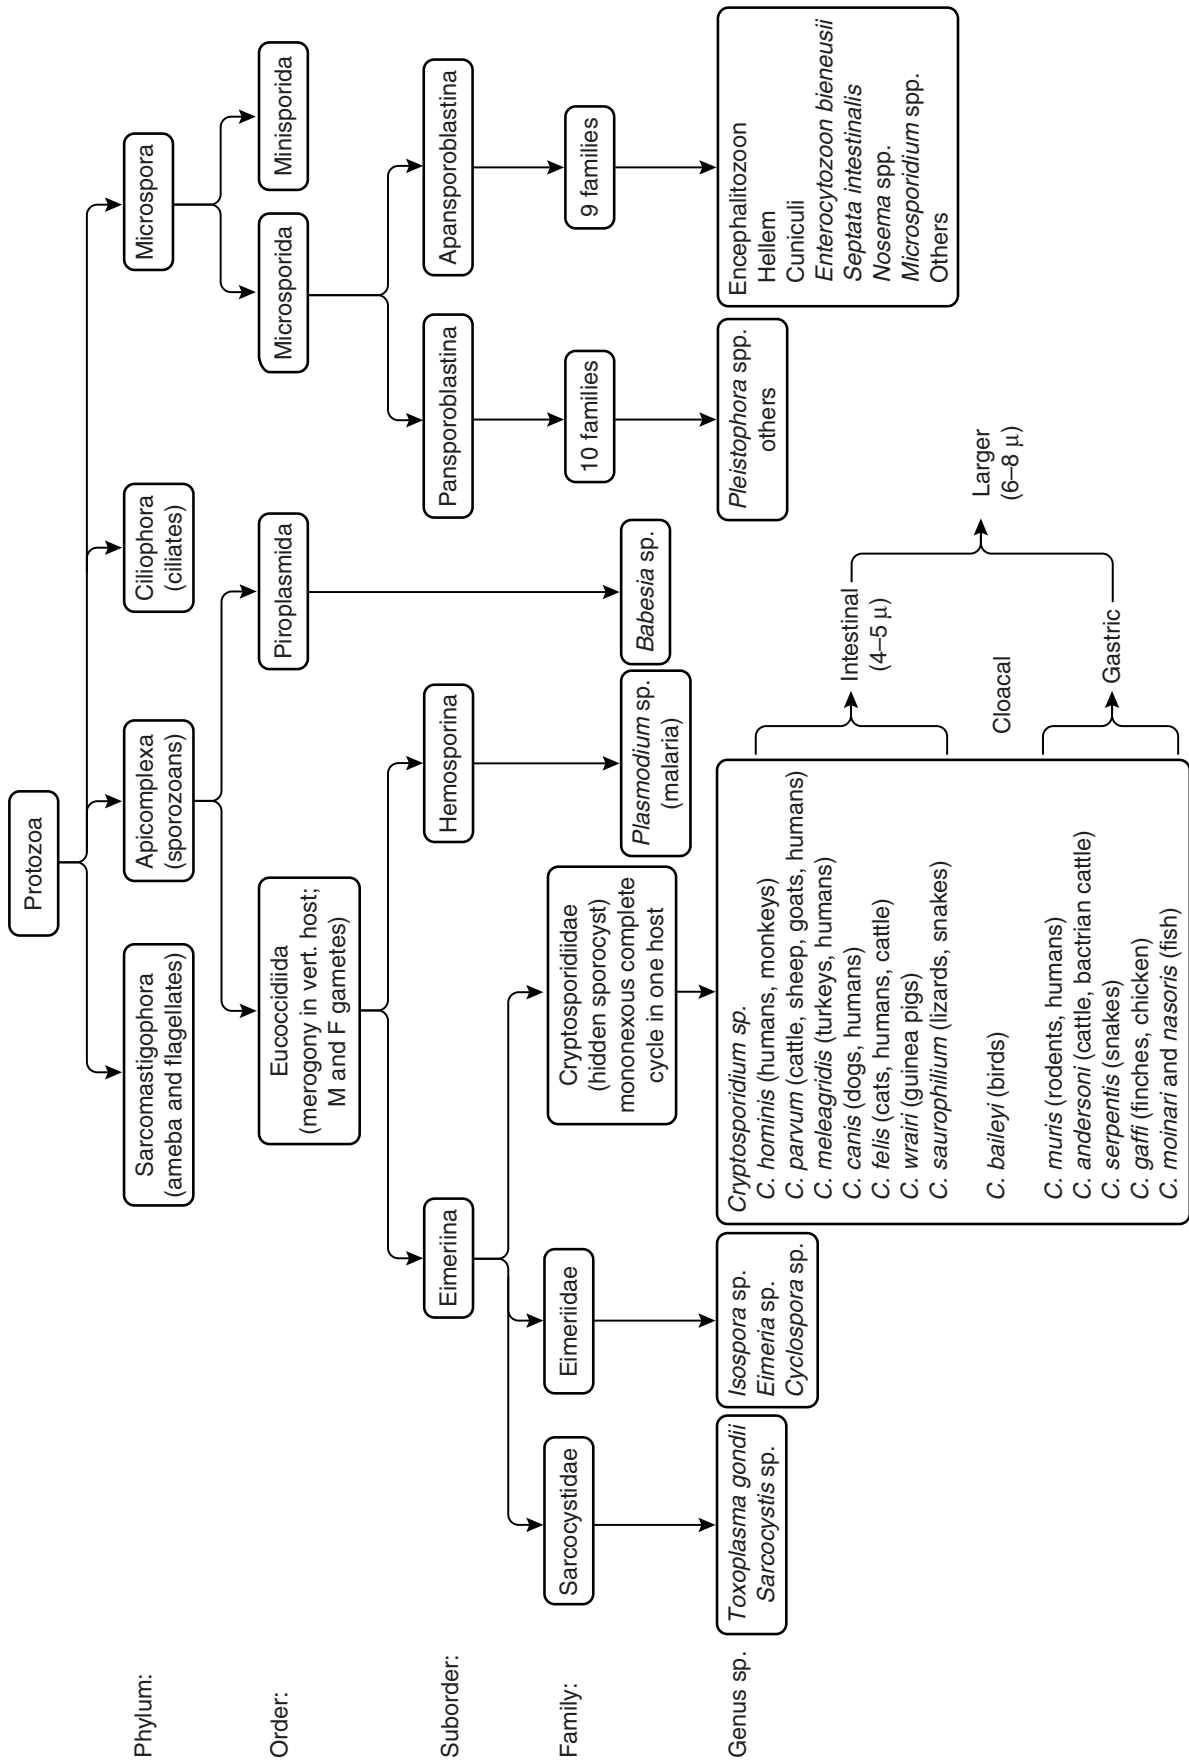

wages and productivity.<sup>4-6</sup> Since then, *Cryptosporidium* has been recognized to occur even more often in immunocompetent persons, and it is a leading cause of endemic childhood diarrhea in developing areas and waterborne diarrheal outbreaks in developed countries.

## Taxonomy

The taxonomy of the genus *Cryptosporidium* is incomplete and evolving. The family Cryptosporidiidae belongs to the phylum Apicomplexa characterized by an anterior (or apical) polar complex (with apical rings, micronemes, and subpellicular microtubules), which allows penetration into host cells. The coccidia are further classified based on their life cycles into the class Sporozoasida (locomotion by flexion, gliding, or undulation) and subclass Coccidiasina (sporozoite formation). The vertebrate diarrheal coccidia belong to the order Eucoccidiorida (Eucoccidiida) and suborder Eimeriorina (Eimeriina) based on merogony within vertebrate hosts and independent development of male and female gametocytes. This separates them from other pathogenic apicomplexan protozoa (*Plasmodium* and *Babesia*). The species and genotypes of *Cryptosporidium* are shown in Figure 88-1 and are discussed in the section on Epidemiology and Ecology.

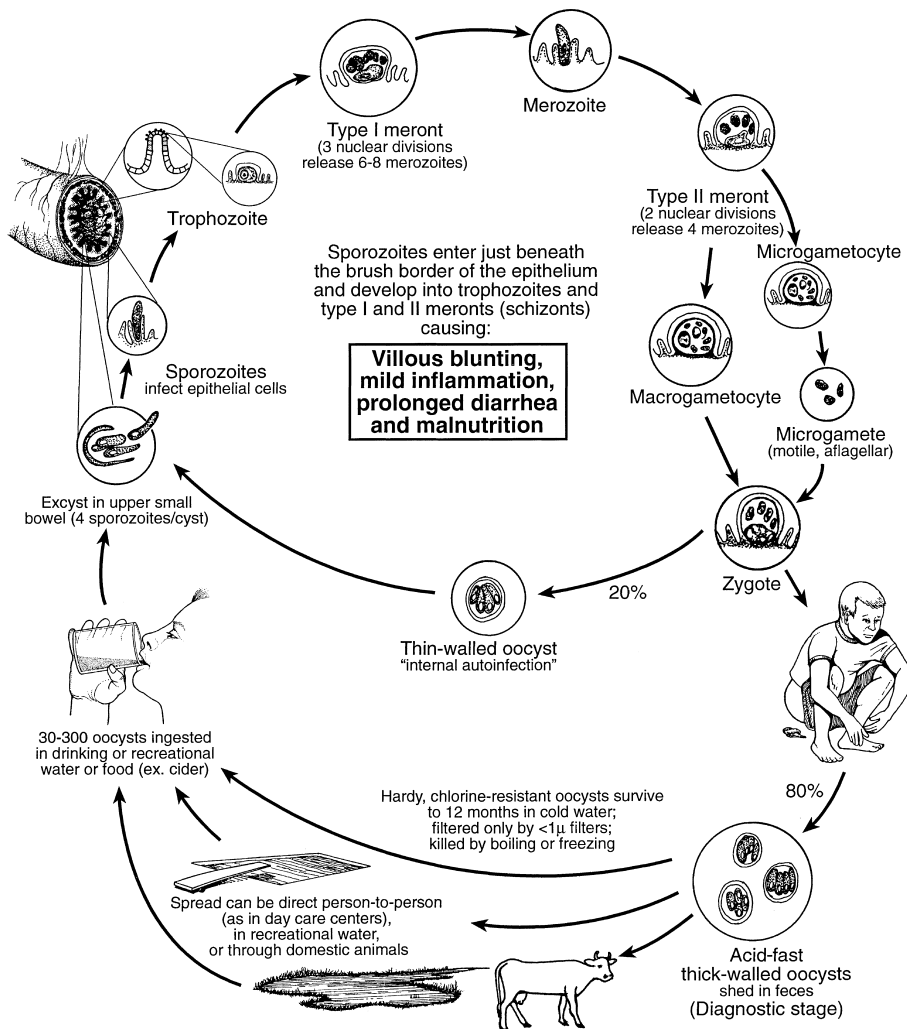

## Life Cycle

*Cryptosporidium* are monoxenous (i.e., the complete life cycle occurs in a single host) in contrast to *Plasmodium* spp. and *Sarcocystis* spp., which require two hosts. *Cryptosporidium* oocysts are thick-walled and 3 to 6  $\mu\text{m}$ , which when ingested by the host, excyst within the lumen of the small intestine to release four infective sporozoites. Sporozoite attachment results in the formation of a unique intracellular but extracytoplasmic parasitophorous vacuole within which they develop into trophozoites and subsequently type 1 meronts (schizonts). These reproduce asexually with three nuclear divisions to release eight type 1 merozoites, which invade nearby cells and develop into type 2 meronts or into trophozoites to complete the asexual reproductive cycle. The merozoites are similar in morphology and function to the sporozoites, and are capable of reinfecting other host cells, thereby reinitiating the asexual part of the cycle in the same host. The perpetuation of the asexual stage of the life cycle, a property also shared by *Isospora*, is probably responsible for persistent and severe infections in hosts who do not have repeated exposure to these parasites. Type 2 meronts undergo two nuclear divisions and release four type 2 merozoites, which reinfect the epithelium and develop into male (microgamont) or female (macrogamete) forms. The microgamont releases microgametes, which penetrate the macrogamete to form a zygote, which can then develop into a thin-walled autoinfectious oocyst (approximately 20% of the time) or a thick-walled oocyst (approximately 80%), which is shed in stool. The average incubation period (time from ingestion to disease manifestation) is approximately 1 week. Remarkably, the entire asexual and sexual phases of development take place just beneath the luminal cell membrane of epithelial cells without deeper cellular or tissue invasion, even in severely immunocompromised patients.<sup>7</sup>

**FIGURE 88-1** Taxonomy of *Cryptosporidium* and related protozoa. *C. hominis* has been responsible for most human outbreaks in Milwaukee, Las Vegas, Atlanta, Washington, D.C., Florida, and British Columbia, Canada. Some outbreaks in Minnesota, Pennsylvania and British Columbia and the United Kingdom have also been with the bovine strain *C. parvum*.

# *Cryptosporidium parvum*\*

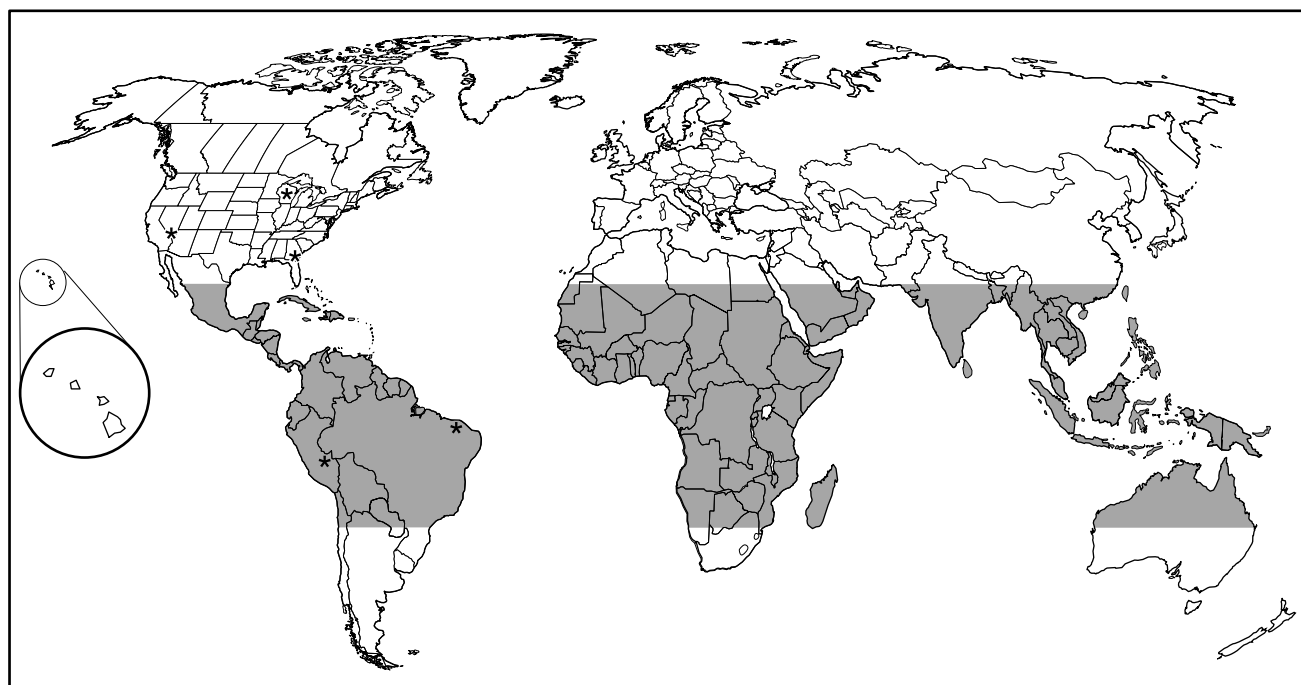

\*Although less is known about the life cycles of *Cyclospora* and *Isospora*, both penetrate into epithelial cytoplasm and both *Cyclospora* and *Isospora* (which are larger), unlike *Cryptosporidium*, require development outside the host, and thus lack the same risk for secondary person-to-person spread. All three are acid fast.

## EPIDEMIOLOGY AND ECOLOGY

Over 20 species were originally named in the family Cryptosporidiidae based on the host they infected, but these different species were subsequently shown not to be host-specific and are no longer distinguished. On the basis of size and biologic, ribosomal RNA, and genetic studies, three larger "gastric" (or cloacal) species (*C. muris*, *C. baileyi*, and *C. serpentis*, predominantly from mice, birds/chickens, and snakes, respectively) can be distinguished from the smaller, intestinal species more closely related to *C. parvum*, including *C. hominis*, *C. parvum*, *C. wrairi* (in guinea pigs), *C. meleagridis* (in birds, especially turkeys), *C. felis* (in cats), and possibly *C. saurophilum* (in snakes), *C. andersoni* (in ruminants), *C. nasorum* (in fish), and others. Species that are known to infect humans are: *Cryptosporidium hominis* (formerly called type 1 or "human" *C. parvum*), which primarily infects humans<sup>8-10</sup>; *C. parvum*

(formerly called type 2 or "bovine"), which infects humans and cattle; *C. meleagridis* from turkeys<sup>11,12</sup> and *C. felis* from cats, as well as dog, pig, and monkey genotypes<sup>13-15</sup>; and possibly *Cryptosporidium muris*, which commonly infects mice and sometimes cattle (see Fig. 88-1 adapted from Xiao and colleagues<sup>16</sup>).<sup>17-19</sup> The significance of the molecular analyses of *C. parvum/hominis* isolates remains to be fully defined; one report suggests no differences in age, antecedent stunting, or association with diarrhea or its duration, but longer shedding with *C. hominis* (type 1) than with *C. parvum* (type 2) in children in Peru.<sup>14</sup>

*Cryptosporidium* oocysts have been found in 87% of the raw water samples tested from the United States and Canada.<sup>20</sup> A linear regression model found that the presence of oocysts correlated with the level of watershed protection, the amount of coliform bacteria, and the turbidity, pH, and

\*Waterborne outbreaks caused by *Cryptosporidium*

temperature of the water. Domesticated animals are probably the primary reservoir for *C. parvum*, although patients with AIDS and others with cryptosporidiosis may also contribute, since some may excrete millions of oocysts a day, which can survive for months in sewage.

*Cryptosporidium* oocysts possess a unique set of five characteristics that make the organism such a common and problematic threat.<sup>21</sup> First, they are highly infectious: The median infectious dose in healthy adult volunteers is 132 oocysts,<sup>22</sup> although a mathematical model based on the Milwaukee outbreak estimated that some people could have been infected after ingestion of as few as 1 to 10 oocysts. This infectivity probably accounts for the high rate of person-to-person transmission, ranging from 5.4% of household contacts of adults infected in the Milwaukee outbreak developing symptomatic disease to 19% of family members of infected children in Fortaleza, Brazil, developing disease or seroconversion.<sup>5,23</sup> *Cryptosporidium* also may spread among children in day-care centers<sup>24</sup> and among the elderly in hospitals.<sup>25,26</sup>

Second, the size and composition of cryptosporidial oocysts makes them highly resistant to water treatment. The oocysts measure 3 to 6  $\mu\text{m}$  in diameter, which enables them to pass through most conventional filters. Only water filters capable of removing particles smaller than 1  $\mu\text{m}$  are reasonably effective at removing *Cryptosporidium*, but even these may fail.<sup>27</sup> Effective filters include reverse osmosis filters and those rated as “absolute” at 1  $\mu\text{m}$  but not “nominal” 1- $\mu\text{m}$  filters.<sup>28</sup> Third, *Cryptosporidium* oocysts are highly resistant to chlorination, remaining infectious even after exposure for 30 minutes to 80 ppm chlorine (100 times the acceptable dose for elimination of coliform bacteria).<sup>29</sup> The cysts are inactivated, however, by ozone, freezing, or heating (to 72°C for 1 minute or 45°C for 10–20 minutes).<sup>29,30</sup>

Fourth, the full development of *Cryptosporidium* oocysts by the time they are excreted to a promptly infectious stage means that they can be readily spread by direct person-to-person contact, a key determinant of the epidemiology of cryptosporidial infections.<sup>21,23</sup> The fifth problematic characteristic of *Cryptosporidia* is that most genotypes (other than type 1, *C. hominis*) are widely zoonotic. Unlike most outbreak isolates of cryptosporidiosis in the United States and Canada, which are genotype 1 (*C. hominis*),<sup>31–33</sup> most sporadic cases and outbreaks in the United Kingdom and Switzerland are with the bovine (type 2) *C. parvum* genotype, some of which have been associated with ingestion of raw milk or cream.<sup>32–35</sup>

Cryptosporidial diarrhea is seen primarily in four settings: endemic childhood diarrhea in developing areas, traveler's diarrhea in visitors to developing areas, protracted diarrhea in immunocompromised patients, and waterborne disease outbreaks in developed countries. Seroprevalence studies reflect these settings, with seropositivity ranging from 58% in adolescents in Oklahoma<sup>36</sup> to 50% by 8 to 10 years of age in China and 95% by age 2 years in a poor community in northeastern Brazil.<sup>37</sup> In all settings, *Cryptosporidium* is strongly associated with diarrhea, although asymptomatic infections do occur. Compiling data from 78 studies published before 1993, Adal and colleagues<sup>19</sup> found an overall prevalence of *Cryptosporidium* in 6.1% of diarrhea patients and 1.5% of controls in developing countries, and 2.15% of patients and 0.15% of controls in developed countries. Recent data from 19 studies published with controls from 1994–2003 indicate the overall prevalence of *Cryptosporidium* infection is even higher: 12.7% in immunocompetent patients in developing countries who present with diarrhea and an asymptomatic carriage of 4.5%,<sup>38–53</sup> whereas in developed countries the prevalence is 2.3% in diarrhea cases and 1.2% asymptomatic carriage in controls (Table 88-1).<sup>54–56</sup>

**Table 88-1** Frequency of Cryptosporidiosis among Immunocompetent Symptomatic and Asymptomatic Individuals in Developing and Developed Countries 1994–2003

Area	Patients with Diarrhea	Controls Without Diarrhea
Asia/Africa/ Latin America (n = 16) <sup>38–53</sup>	849/6669 (12.7%)	346/7539 (4.5%)
North America/ Europe/Australia (n = 3) <sup>54–56</sup>	25/1049 (2.3%)	67/5624 (1.2%)

The higher incidence of cryptosporidiosis in developing areas is thought to be due to greater exposure to the organism because of poor sanitation and crowded living conditions. Specific risk factors for acquisition in children include male sex, keeping animals in the house, and weaning.<sup>57</sup> In most studies breastfeeding is protective and children with cryptosporidial diarrhea are less likely to be breastfed.<sup>58</sup> While this may be due in part to passive transfer of immunity, it may also be due to increased exposure to potentially contaminated food and water at weaning.<sup>59</sup>

Those most severely affected by *Cryptosporidium* are immunocompromised patients, especially those with AIDS, in whom the disease can be fulminant and fatal. Adal and colleagues, compiling results from 22 studies published before 1993, found that 13.8% and 24% of patients with AIDS and diarrhea in developed and developing areas, respectively, had *Cryptosporidium* compared with only 0% to 5% of AIDS patients without diarrhea.<sup>19</sup> In five studies published with controls for 1994 through 2003 from developing countries of Africa, Asia, and Latin America, immunodeficient patients (including HIV and malignancies) have a prevalence of 16.1% in cases with diarrhea and 2.2% asymptomatic carriage of *Cryptosporidium* (Table 88-2).<sup>60–64</sup> Studies in immunocompromised patients with controls from developed countries since 1994 were not found.

Patients with AIDS are prone to developing debilitating disease with cryptosporidiosis. In the Nevada outbreak, 61 of the 2270 known HIV-infected patients in the area developed diarrhea, and 32 of these died within 6 months; this is similar to the high mortality in the Milwaukee outbreak, in which 48 of 82 infected patients with AIDS died within a year, with excess mortality largely attributable to the cryptosporidial illnesses.<sup>65,66</sup>

**Table 88-2** Frequency of Cryptosporidiosis among Immunocompromised Symptomatic and Asymptomatic Individuals in Developing Countries, 1994–2003

Area	Patients with Diarrhea	Controls Without Diarrhea
Asia/Africa/ Latin America (n = 5) <sup>60–64</sup>	73/453 (16.1%)	7/324 (2.2%)

In developed countries, cryptosporidiosis is also sporadic. The prevalence is increased in dairy farmers and other persons who have contact with cattle.<sup>67</sup> Small outbreaks have been reported in day-care centers and veterinary and health-care settings. The largest outbreaks, however, have been waterborne. *Cryptosporidium* is the most common cause of recreational water outbreaks due to contaminated lakes and swimming pools. In 1999–2000, *C. parvum* accounted for the largest percentage (44%) of waterborne outbreaks involving gastroenteritis, 61% occurring in treated systems (i.e., pools).<sup>68</sup>

Spring is the time of peak incidence, presumably due to the propensity for heavy rains during that season to cause flooding and subsequent contamination of source water. Numerous large community-based waterborne outbreaks of *Cryptosporidium* have been reported since 1984, affecting hundreds of thousands of people.<sup>69</sup> By far the largest of these was the 1993 outbreak in Milwaukee, Wisconsin, in which an estimated 403,000 people developed diarrhea due to a combination of source water contamination and transient impairment of prefiltration processing. Of note, the water quality during that outbreak met all U.S. federal drinking water standards at that time.<sup>4</sup> The federal standards for turbidity were strengthened as a result, but a 1994 outbreak affecting over 100 people in Las Vegas, Nevada, occurred even when the water met these tougher standards (i.e., not exceeding 0.17 nephelometric turbidity units).<sup>65</sup>

## DISEASE

### Clinical Manifestations

The clinical manifestations of cryptosporidiosis are indistinguishable from those of giardiasis, isosporiasis, and cyclosporiasis. Clinical illness is characterized by watery diarrhea without red blood cells or leukocytes and may be associated with one or more nonspecific symptoms and signs, such as cramping abdominal pain, anorexia, malaise, flatulence, nausea, vomiting, and low-grade fever. When right upper quadrant pain is present in patients with AIDS, suggesting biliary tract involvement, it should point toward cryptosporidiosis, although cases of isosporiasis or cyclosporiasis with similar clinical manifestations have been reported.

The clinical manifestations of cryptosporidial infection vary according to the immune status of the host. In the immunocompetent host, the onset is usually acute, occurs after an incubation period of 2 to 14 days, and is generally self-limited. The clinical spectrum ranges from asymptomatic passage of oocysts to severe cholera-like gastroenteritis with biliary tract disease. The hallmark of cryptosporidial infection is diarrhea, which is usually described as watery, voluminous, and occasionally explosive and foul smelling. Additional symptoms seen in more than 80% of patients in the Milwaukee outbreak were abdominal cramps, fatigue, and anorexia.<sup>4,5</sup> In addition, more than half of patients may experience weight loss, nausea, low-grade fever (up to 38°C), chills, sweats, myalgias, and headache. The illness may be quite prolonged, lasting 10 to 14 days, with an average of 12 stools per day during the peak of the illness and often significant weight loss (median 4.5 kg in the Milwaukee outbreak). Although their HIV status is not specified, at Mulago Hospital

in Kampala, Uganda, 31% of children hospitalized with persistent diarrhea and 22% with acute diarrhea (vs. 8.5% without diarrhea) had *Cryptosporidium* infections, often with wasting and stunting.<sup>70</sup>

Asymptomatic infection can occur in immunocompetent and immunodeficient patients. In one series, as many as 63% of childhood cryptosporidial infections in Peru were asymptomatic, although these “subclinical” infections may have lasting consequences on growth and development.<sup>71–73</sup> In New York, asymptomatic cryptosporidiosis was documented in 6.4% of immunocompetent and 22% of immunodeficient children.<sup>74</sup> Excretion of oocysts after resolution of clinical symptoms can continue for prolonged periods.<sup>72</sup> Relapses of cryptosporidial infection have been considered rare, although 39% of the patients infected in the Milwaukee outbreak had a brief recurrence of diarrhea after a period of normal stools.

In immunocompromised patients, cryptosporidiosis is usually much more prolonged or severe. In particular, patients with AIDS often have chronic intermittent diarrhea, with recurring 3- to 30-day episodes lasting up to 14 months. Those with low CD4 lymphocyte counts are prone to develop protracted, fulminant, and rapidly fatal diarrhea. Cryptosporidiosis in HIV-positive patients can be asymptomatic in 4%, transient in 29%, chronic in 60%, or fulminant (greater than 2 L of stool per day) in 8%. Mean survival in these HIV patients with *Cryptosporidium* co-infection was 25 weeks in the study by Blanshard and associates.<sup>75</sup> Patients who develop fulminant disease usually have fewer than 50 CD4 cells per microliter and sharply limited survival of only 5 weeks. Spontaneous clinical remission is associated with higher lymphocyte<sup>76</sup> or CD4 count.<sup>77</sup> In the Nevada outbreak in 1994, two-thirds of the HIV-infected patients with cryptosporidiosis developed chronic disease, with a median weight loss of 13.6 kg, and nausea, vomiting, and abdominal cramping occurred in at least 80%. Over half of these patients died within 6 months of the onset of the outbreak, of whom 60% had cryptosporidiosis listed as a cause of death on their death certificates.<sup>65</sup> Cryptosporidiosis has also been reported as an opportunistic pathogen in patients immunosuppressed due to cytotoxic chemotherapy or congenital immunodeficiencies.

Extraintestinal disease due to *Cryptosporidium* has been seen in immunocompromised patients, especially those in the late stages of AIDS (CD4 counts less than 50/ $\mu$ L). By far the most common site is the biliary tree, manifestations of which include sclerosing cholangitis and acalculous cholecystitis. Direct luminal spread of organisms from the duodenum is believed to be responsible. The hallmark symptom is right upper quadrant pain, which can resemble that of chronic or acute calculous cholecystitis. There have also been reports of respiratory cryptosporidiosis; in one study, 7 of 43 patients with AIDS and cryptosporidial diarrhea had oocysts isolated in sputum, although it was probably nonpathogenic in six.<sup>78</sup> One patient with AIDS had cryptosporidial sinusitis that improved during therapy with spiramycin.<sup>79</sup>

## Pathology

*Cryptosporidium* is primarily a pathogen of the small bowel producing villous blunting, submucosal edema, and mononuclear inflammatory infiltrates in the lamina propria.

This is often associated with evidence of malabsorption, such as abnormal D-xylose tests and evidence of intestinal barrier disruption by lactulose-mannitol permeability ratios.<sup>80–83</sup> In the case of *Cryptosporidium*, various life cycle forms can be seen just beneath the apical enterocyte membranes; ultrastructurally, they reside in vacuoles with specialized basal membrane folds called “feeder organelles.”<sup>83</sup>

## Complications

Cryptosporidial enteritis is usually a self-limited, nonfatal illness in normal hosts. As such, the only immediate complication of concern is volume depletion from heavy diarrhea and inadequate fluid intake, especially in young children and the elderly. This is usually treatable with oral rehydration therapy.

*Cryptosporidium parvum* in children has a lasting adverse effect on linear (height) growth and correlated with impaired cognitive function.<sup>72,73</sup> Infected children who became stunted may not catch up in either weight or height, and exhibit the deficit even 1 year after infection.<sup>72</sup> However, there are more subtle, long-term detrimental effects of childhood cryptosporidiosis, including both an increased overall diarrheal burden over several months following an attack and impaired growth, even with so-called asymptomatic infections.<sup>71,72,84</sup> As such, the public health importance of these infections in developing countries is likely to be far greater than generally recognized.

The life-threatening complications of coccidian enteritis occur most often in chronic disease, which is largely confined to immunocompromised patients. In these cases severe infection can lead to chronic malabsorption, which may be treated by total parenteral nutrition or novel approaches to enteral, glutamine-based nutrition.<sup>85,86</sup> Supportive therapy is especially important in cryptosporidiosis, which has no uniformly effective antimicrobial treatment at this time. Moreover, extraintestinal disease, especially of the biliary tract, can lead to substantial morbidity from chronic pain and mortality from biliary obstruction.

## PATHOGENESIS AND IMMUNITY

A great mystery in the study of cryptosporidiosis is how it produces profound inflammatory and destructive pathophysiology without tissue invasion. A simple explanation would be the elaboration of an enterotoxin or cytotoxin, although thorough investigation has failed to discover such a toxin.<sup>87</sup> Guarino and associates<sup>88,89</sup> reported an enterotoxic effect of stool from infected humans or calves on intestinal strips or cells mounted in Ussing chambers, although they were unable to show that this secretagogue was parasite-derived rather than host-derived.

Most research has focused on the direct epithelial effects of infection with *Cryptosporidium*. Several observations on experimental porcine infection suggest that part of the symptomatology of cryptosporidiosis may be due to malabsorption by blunted or inflamed villi coupled with intact fluid secretion from the crypts. Prostaglandins also appear to play a role in this imbalance, but the details of this interaction are still unclear.<sup>85,90</sup> Two studies of intestinal epithelial cells in tissue culture have found destructive effects of *Cryptosporidium*

infection, including loss of barrier integrity and moderate cell injury,<sup>83,91</sup> effects that are confirmed in vivo by increased lactulose-mannitol excretion ratios in patients with cryptosporidiosis.<sup>81,82</sup> Some of this damage may be due to release of pro-inflammatory cytokines (such as TNF- $\alpha$  and IL-8) induced by *Cryptosporidium* infection.<sup>58,92</sup> Recent work has suggested that substance P, a neuropeptide, may also play a role in mediating diarrhea in human cryptosporidiosis.<sup>93</sup>

The severe nature of intestinal coccidiosis in patients with AIDS suggests that cell-mediated immunity is essential to clearance of these organisms. This is supported by several observations. First, humoral immune responses to *Cryptosporidium* are quite strong in patients with AIDS, perhaps even greater than those in immunocompetent individuals.<sup>94</sup> Second, humoral responses are not associated with clearance of infection. This has been shown in mice,<sup>95</sup> as well as in HIV-infected patients who develop serum and intestinal antibodies but fail to clear infections.<sup>94,96</sup> Third, peripheral blood mononuclear cells (PBMCs) from patients with AIDS do not have normal proliferative responses to cryptosporidial antigens even though they may respond to mitogens.<sup>97</sup> Finally, experimental mice become susceptible to cryptosporidial infection after depletion of functional T helper lymphocytes or treatment with dexamethasone.<sup>98,99</sup> On the other hand, a role for humoral immunity in the resistance to *Cryptosporidium* is suggested by the severe disease seen in patients with congenital hypogammaglobulinemias but normal T-cell function.<sup>100,101</sup>

One hypothesis is that the cytokine interferon- $\gamma$  (IFN- $\gamma$ ) may be required for an effective immune response to *Cryptosporidium*. IFN- $\gamma$  is produced primarily by the Th1 subset of CD4 lymphocytes, which also release interleukin (IL)-2 but not IL-4, IL-5, or IL-10. Furthermore patients with advanced HIV infections are often deficient in Th1 lymphocytes.<sup>102</sup> Experimental mice can be rendered susceptible to cryptosporidiosis if treated with antibodies to IFN- $\gamma$ , and mice immunosuppressed with dexamethasone can be protected from the organism by treatment with high doses of IFN- $\gamma$ .<sup>98,103</sup> Gomez Morales and coworkers<sup>97</sup> found high amounts of IFN- $\gamma$  released in response to cryptosporidial antigens by PBMCs from immunocompetent patients only if they had a history of transient cryptosporidiosis. In experimentally infected volunteers with *Cryptosporidium*, IFN- $\gamma$  expression occurs in immunocompetent subjects with self-limited infection and correlates with prior exposure to *Cryptosporidium* and resistance to re-infection.<sup>104</sup> Finally, selective lack of IFN- $\gamma$  production by lymphocytes in response to cryptosporidial antigens in an HIV-negative child was associated with chronic and ultimately fatal cryptosporidiosis; a thorough immunologic evaluation revealed no other abnormalities.<sup>105</sup>

Naive volunteers appear to have increased IL-15 expression in their intestinal mucosa when experimentally infected with *Cryptosporidium* and this is correlated with no or low numbers of oocyte shedding.<sup>106</sup> In contrast, TNF- $\alpha$ , IL-1 $\beta$ ,<sup>107</sup> and IL-4<sup>106</sup> do not appear to be associated with symptoms or *Cryptosporidium* oocyst shedding in humans. In a recent study, significant elevations of fecal IL-8, IL-13, and TNF- $\alpha$  receptor 1 have been described in *Cryptosporidium*-infected children in Haiti,<sup>58</sup> and mildly increased fecal IL-8, TNF- $\alpha$ , and lactoferrin in some *Cryptosporidium*-infected children in Brazil.<sup>108</sup>

## DIAGNOSIS

Cryptosporidiosis should be suspected in any patient presenting with watery diarrhea, abdominal cramps, and nausea, particularly if symptoms last more than a few days. Although persistent diarrhea (>1–2 weeks) in travelers, those with recreational water exposure, or immunocompromised individuals should raise concern for cryptosporidiosis, no obvious environmental exposure history is necessary, since the organism may be transmitted by so many different means. There are no characteristic findings on physical examination or laboratory or radiologic analysis, although volume depletion, metabolic alkalosis, and hypokalemia may be seen in more severe cases. Children in developing areas as well as patients with HIV respond to *C. parvum* with mild intestinal inflammation with detectable fecal lactoferrin (a sensitive marker for the presence of fecal leukocytes)<sup>58,81,108</sup> and mildly elevated IL-8 and TNF- $\alpha$ R1.<sup>58</sup> In contrast, fecal lactoferrin was not observed in healthy U.S. adults experimentally infected with *C. parvum*.<sup>108</sup>

In immunocompromised patients, the findings are characteristically more severe and prolonged. In addition, if the biliary tree is involved, there may be elevations in alkaline phosphatase and transaminases and irregular ductal strictures and dilations on ultrasound or endoscopic retrograde cholangiopancreatography (ERCP).<sup>109</sup> Pulmonary involvement can produce various infiltrates on chest radiograph.<sup>78</sup>

Oocyst shedding in cryptosporidiosis can be intermittent and up to three stool specimens may be needed for diagnosis.<sup>110,111</sup> The diagnosis can be confirmed by observation of the oocysts in stool or luminal fluids. Using a modified Kinyoun acid-fast stain, oocysts appear as red spheres 3 to 6  $\mu$ m in diameter; no other organisms should be easily confused with *Cryptosporidium* based on size and appearance (Plate 88-1). Unfortunately, acid-fast staining is relatively insensitive, requiring 10,000 oocysts per gram of watery stool and 500,000 per gram of formed stool to make the diagnosis. There are several immunologic techniques, including immunofluorescence and enzyme-linked immunoassays, which are commercially available through several laboratories. These techniques have sensitivity and specificity approaching 100% for *C. parvum*; and require less technician time and experience.<sup>112–114</sup> Serologic testing for antibodies to cryptosporidial antigens is available for epidemiologic surveys, but is of little help in the diagnostic evaluation of patients.

While the immunoassays are adequate for clinical diagnosis of cryptosporidiosis, they are not sensitive enough to detect oocysts in environmental samples or in epidemiologic surveys of asymptomatic contacts, since the oocyte numbers are too low. Various concentration techniques including formalin–ethyl acetate sedimentation and disposable parasite concentrators have been used to increase the efficiency of oocyst recovery for immunoassays; as few as 5000 oocysts per gram of stool can be detected by these methods.<sup>115,116</sup> Polymerase chain reaction (PCR) testing is more sensitive, with detection of 50 to 500 oocysts per milliliter of liquid stool or less than 1 pg of DNA and less than 10 oocysts from environmental samples.<sup>117–119</sup>

## TREATMENT AND PROGNOSIS

Cryptosporidiosis in immunocompetent patients is self-limited, and symptomatic therapy should be directed at

rehydration and nutrition. Oral rehydration solution should be used as needed to prevent volume depletion. Antimotility agents (loperamide, diphenoxylate, or other opiates) may be used once more invasive conditions (e.g., bacterial enteritis, amebiasis, or pseudomembranous colitis) have been excluded. Glutamine appears to be more effective in driving electrolyte and water absorption in *Cryptosporidium*-infected porcine intestine and has the advantage of enhancing injury repair.<sup>85,86</sup>

The disease is much more problematic in immunocompromised patients, since it is often not self-limited and there is no acceptable antimicrobial treatment currently available. Dramatic improvements in HIV-related cryptosporidiosis after initiation of highly active antiretroviral therapy, including complete eradication of the parasite in patients, have been documented.<sup>120,121</sup> In a survey conducted in France from January 1995 to December 1996, there was approximately a 60% decline in the prevalence of cryptosporidiosis that coincided with the widespread use of protease inhibitors.<sup>122</sup> Recent data suggests that protease inhibitors, particularly indinavir, may directly interfere with the life cycle of *Cryptosporidium*.<sup>123</sup>

Over 100 antibacterial and antiparasitic agents have been tried to no avail. In a small double-blind, placebo-controlled trial, the nonabsorbable aminoglycoside paromomycin has been shown to reduce the frequency and intensity of diarrhea in patients with AIDS and chronic cryptosporidiosis.<sup>124</sup> In addition, inhaled paromomycin was associated with improvement in one reported case of respiratory cryptosporidiosis.<sup>125</sup> The optimal dose has not yet been established. White and coworkers<sup>124</sup> used 25 to 35 mg/kg/day for 14 days; larger doses (up to 50 mg/kg/day) were shown to be more effective in animal models, but vestibular toxicity has been reported at these doses in humans.<sup>124</sup> Maintenance therapy may be indicated in patients with AIDS and low CD4 counts to prevent relapse. A recent randomized, controlled trial has shown that paromomycin was no more effective than placebo in patients with advanced AIDS.<sup>126</sup>

The most promising new drug for the treatment of cryptosporidiosis is nitazoxanide, a broad-spectrum antiparasitic agent. In a double-blind, controlled study in pediatric patients with diarrhea, nitazoxanide was associated with the resolution of diarrhea in 88% of children compared to 38% on placebo.<sup>127</sup> In another study of malnourished children with cryptosporidial diarrhea, a significant 56% had a resolution of diarrhea and 52% had parasitological response with 3 days of treatment compared with 23% and 14%, respectively, in controls. However, no significant effect was seen in HIV-seropositive pediatric patients.<sup>128</sup> Nitazoxanide elixir is approved for treatment of cryptosporidiosis in children aged 1 to 11 years in the United States. In children 12-to-47 months old, a dose of 100 mg every 12 hours is used, and in older children (4 to 11 years), 200 mg every 12 hours orally is recommended.

Several other agents that have been studied include azithromycin, which at 900 to 1200 mg/day reduced the severity of diarrhea and oocyst shedding, but only in patients in whom appropriate drug levels were obtained.<sup>129</sup> Azithromycin at 500 mg daily was found to be ineffective compared to letrozuril and paromomycin,<sup>130</sup> while reduced oocyst excretion and modest clinical improvement were noted with open label combination azithromycin (600 mg qd for 4 weeks) and paromomycin (1 g bid for 8 weeks).<sup>131</sup> Two phase I trials of letrozuril (50–100 mg/day) have shown modest, short-lived response in 66%; however, clinical relapse and worsening

diarrhea occurred in 65% of the responders.<sup>132,133</sup> There are reports of responses to spiramycin, including one patient with extraintestinal disease.<sup>79</sup> In a double-blind, placebo-controlled study of immunocompetent infants in Costa Rica, infants treated with spiramycin had significantly decreased duration of diarrhea and excretion of oocysts.<sup>134</sup> Bovine hyperimmune colostrum (marketed as lactobin) was reported to eradicate the organism in a child with AIDS and chronic cryptosporidiosis.<sup>135</sup> In another case report, a 38-year-old HIV patient with 6 to 12 L of stool/day for 3 months had resolution within 48 hours of being treated with hyperimmune bovine colostrum and remained asymptomatic for 3 months.<sup>136</sup> Conclusive support for the use of hyperimmune colostrum, however, has not been forthcoming.

Results of non-double-blinded therapeutic studies of cryptosporidiosis should be interpreted with caution: Immunosuppressed patients tend to have intermittent diarrhea that can improve or worsen according to the patient's CD4 count, and clinical responses do not necessarily accompany eradication of oocysts from the stools. Endpoints for successful therapy should include both the cessation of diarrhea and other clinical manifestations, as well as the absence of oocysts in the stools; relapses are frequent.

Symptomatic therapy in patients with AIDS has also been disappointing, since the profound diarrhea may be refractory to antimotility agents. Clinical improvement has been reported with the somatostatin analogue octreotide (100–300 µg subcutaneously 3 times daily), although a placebo-controlled trial found no benefit<sup>137–140</sup>; moreover, this agent is prohibitively expensive for widespread use. The related oral drug vapreotide was found to improve AIDS-related chronic diarrhea, but only in patients without cryptosporidiosis.<sup>141</sup> In biliary cryptosporidiosis, cholecystectomy or papillotomy has provided pain relief for many patients, although the operative morbidity of the former may be high.<sup>66,109</sup>

## PREVENTION AND CONTROL

### Current Approaches

The only known way to acquire any of the coccidia is to ingest infectious oocysts; the diseases can be completely prevented by elimination of oocysts from food and water and by avoidance of fecal material from infected people. However, in the case of *Cryptosporidium*, this simple-sounding goal has proved insurmountably difficult to attain. The high infectivity and ubiquitous nature of this organism make complete removal of oocysts during water treatment essential to prevent the disease, and to this day even the most technologically advanced systems cannot reliably achieve this. Since oocysts are extremely resistant to chlorination, water treatment plants must rely on mechanical means to remove them: flocculation, sedimentation, and filtration. In theory, these methods should be adequate to prevent waterborne outbreaks, and in general they are quite effective. However, the Nevada outbreak of 1994 proved that these techniques can fail even without obvious malfunction. Conversely, a massive failure of water treatment, as occurred in Washington, D.C., in 1993, may not be associated with any increase in human cases of cryptosporidiosis.<sup>142</sup>

The problem of inadequate elimination of *Cryptosporidium* from the water supply in developed countries is minuscule in comparison with the problems in developing areas. As noted

earlier, 95% of children in some areas have serologic evidence of infection by age 2 years. Without a source of clean, filtered, or boiled water, improved sanitation, or an effective vaccine, there is no realistic way to prevent cryptosporidial infections in these areas.

Travelers to endemic areas can avoid cryptosporidiosis if they follow the maxim “boil it, cook it, peel it, or forget it.” As mentioned earlier, oocysts are easily killed by heat, so hot beverages and boiled water can be considered safe. Because person-to-person transmission occurs through fecal-oral spread, travelers should probably be advised to wash their hands thoroughly before eating and after contact with young children. These precautions are especially crucial in patients with AIDS, especially those who choose to travel to developing areas during the later stages of their illness when CD4 counts are low.

Because of the ever-present risk of acquisition even in developed countries, patients with AIDS, especially those with CD4 counts less than 100/ $\mu$ L, should be advised of the potentially devastating impact of cryptosporidiosis. Filters that provide the greatest assurance of oocyst removal include those that operate by reverse osmosis, those labeled as absolute 1- $\mu$ m filters, and those labeled as meeting National Sanitation Foundation (NSF) standard no. 53 for cyst removal. The nominal 1- $\mu$ m filter rating is not standardized, and many filters in this category might not be capable of removing 99% of oocysts. Some patients may decide that the inconvenience of boiling or filtering (through “absolute” 1- $\mu$ m filters) all of their drinking water is worth the benefit of protecting themselves from this disease. These patients should also be advised to avoid young farm animals, especially those with diarrhea.

Because of the threat of nosocomial spread of oocysts, strict enteric precautions should be followed when caring for any patient with possible cryptosporidiosis. This includes use of gowns and gloves when fecal soilage is possible and thorough handwashing after all contact. Potentially contaminated medical equipment should be autoclaved. The optimal cleaning compound for contaminated surfaces (e.g., mattresses, toilets) is not known.

## Future Approaches

Much more recent research is devoted to *Cryptosporidium*. Several new approaches to water treatment have been explored, including ozone, ultrasonic waves, and electrochemical treatment, but these are far from ready for widespread use.<sup>29,143</sup> The Centers for Disease Control and Prevention (CDC) pointed to several high-priority objectives for the eventual control of cryptosporidiosis: (1) to assess the public health importance of low-level oocyst contamination of drinking water; (2) to develop guidelines and techniques for notification of the public when oocysts are detected (i.e., to know when boil-water advisories are needed); (3) to identify options for preventing cryptosporidiosis in immunocompromised patients who use the public water supply; and (4) to optimize water sampling techniques to identify *Cryptosporidium* oocysts.<sup>28</sup>

There is considerable interest in vaccine development against *Cryptosporidium*. However, animal models suggest that cell-mediated immunity and intact production of IFN- $\gamma$  are necessary to prevent infection, so the benefit of immunization in patients with AIDS may be limited. A recent trial of a vaccine made from lyophilized oocysts was moderately protective in a bovine model; vaccinated calves had a shorter duration of

diarrhea and excreted fewer oocysts.<sup>144</sup> There have been no vaccines tested in humans yet. A recent study in which previously infected volunteers were rechallenged with *Cryptosporidium* oocysts demonstrated only partial protection against re-infection; although fewer subjects shed oocysts after their second challenge, the rates of diarrhea were the same.<sup>145</sup>

Finally, glutamine, a “conditionally essential” amino acid is effective in driving electrolyte and water absorption in *Cryptosporidium*-infected porcine intestine and has the advantage of enhancing injury repair.<sup>85,86</sup> Clinically, glutamine and its stable derivative alanyl-glutamine have been shown to improve diarrhea and malabsorption in HIV/AIDS patients. These improvements may enhance antiretroviral drug therapy and reduce the emergence of drug resistance<sup>146</sup> as well as ameliorate symptoms associated with severe cryptosporidiosis.<sup>147</sup>

# Cyclospora, Isospora, and Sarcocystis Infections

REBECCA DILLINGHAM  
JEAN W. PAPE  
BARBARA L. HERWALDT  
RICHARD L. GUERRANT

## INTRODUCTION

Like the *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Isospora belli*, and *Sarcocystis* spp. are intestinal coccidia. They are characterized by the fecal excretion of oocysts, which are the product of a sexual cycle of reproduction in the epithelium of the small intestine. The coccidia belong to the phylum Apicomplexa of the subkingdom Protozoa. These organisms are all characterized by sporozoa, with an anterior (or apical) polar complex. This complex, which consists of apical rings, micronemes, and subpellicular microtubules, facilitates penetration into host cells. The coccidia are further subdivided into the class Sporozoasida (having locomotion by flexion, gliding, or undulation) and subclass Coccidiasina (exhibiting sporozoite formation). The intestinal coccidia that infect vertebrate animals belong to the order Eucoccidiorida (Eucoccidiida) and suborder Eimeriorina (Eimeriina).<sup>1,2</sup>

Although some coccidian protozoa have been known for decades to be veterinary pathogens, the existence of and pathogenicity for humans of particular coccidian parasites, such as *C. cayetanensis*, were not recognized until relatively recently.<sup>3</sup> The epidemic of HIV infection in the 1980s heightened medical awareness of *Cryptosporidium* spp. and, to some extent, *C. cayetanensis* and *I. belli*, in part because these parasites can cause severe, protracted diarrheal illnesses in patients with the acquired immunodeficiency syndrome (AIDS).<sup>4</sup> Subsequently, in the mid- and late-1990s, the occurrence of large foodborne outbreaks of cyclosporiasis in North America demonstrated that *C. cayetanensis* can cause diarrhea, sometimes with severe fatigue, in immunocompetent persons as well.<sup>3</sup>

## ■ Cyclospora

### AGENT AND EPIDEMIOLOGY

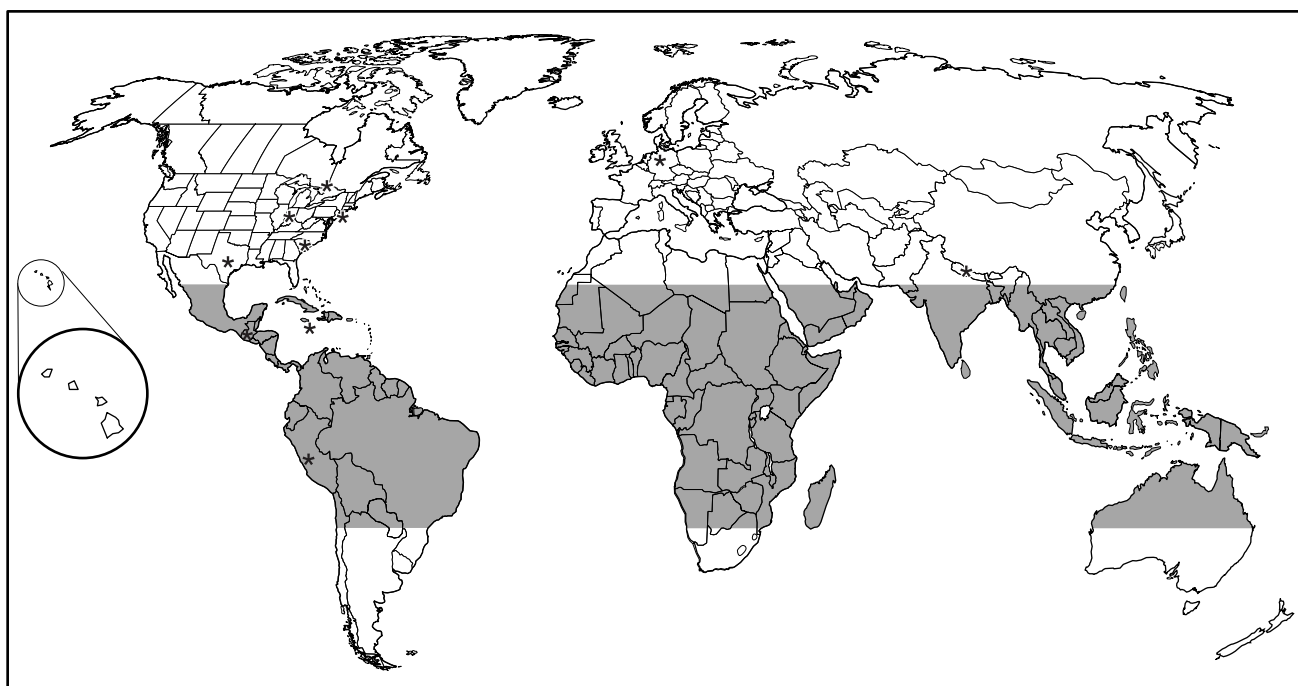

Although the human pathogen *C. cayetanensis* was only named in 1994, other *Cyclospora* species were described first

in moles and myriapods by Eimer (1870), Schneider (1881), and Schaudinn (1901) and subsequently in other animals.<sup>5,6</sup> Several reports that described the pathogen ultimately called *C. cayetanensis* preceded its classification and naming.<sup>7</sup> The first such report was in 1979 by Ashford, who became the first to describe the organism as an “unknown coccidian.” Ashford had isolated the organism in 1977 and 1978 from the stools of three patients in Papua New Guinea, and demonstrated that it sporulated 8 to 11 days after it was excreted in feces.<sup>8</sup> Other reports subsequently described the acid-fast, autofluorescent organism as a possible fungal spore, a coccidian body, an alga-like organism, and a cyanobacterium-like body. It was reported in association with diarrhea in the Caribbean and summertime outbreaks in Nepal and Chicago.<sup>9–13</sup> The organism, *C. cayetanensis*, was named by Ortega and colleagues in 1994 in honor of the researchers’ university, Universidad Peruana Cayetano Heredia. Molecular phylogenetic analysis shows that the organism is closely related to *Eimeria* spp.<sup>1,2</sup> Since 1994, *C. cayetanensis* has been increasingly identified in a number of developing areas and as the etiologic agent of numerous foodborne outbreaks in the United States.<sup>3,14,15</sup>

The complete life cycle, asexual and sexual, of *C. cayetanensis* has been identified in enterocytes in cytoplasmic vacuoles located at the tips of intestinal villi in the small intestine of infected humans. The cytoplasmic location of the vacuoles differentiates *C. cayetanensis* from *Cyclospora* species that infect nonhuman animals.<sup>16</sup> *Cyclospora* oocysts are excreted in stool and, in contrast to the excreted oocysts of *Cryptosporidium* spp., the oocysts are not immediately infectious. Rather, the oocysts must undergo sporulation outside the host. The optimal conditions for sporulation in the environment are not fully understood.<sup>3</sup>

Despite reports that oocysts morphologically similar to those of *C. cayetanensis* have been found in the stools of various animal species, no definitive evidence has been published to date that any nonhuman animal reservoir hosts of *C. cayetanensis* per se (vs. of other *Cyclospora* spp.) exist. Ashford and colleagues<sup>17</sup> have reported oocysts resembling those of *C. cayetanensis* in the stools of chimpanzees in Uganda, and Zepa and associates<sup>18</sup> have described apparent *Cyclospora* oocysts in the stool of a duck raised by a family with *Cyclospora* diarrhea. However, the presence of true infection was not clear from these reports, and morphologic criteria are not sufficient for species identification (B. Herwaldt, personal communication, 2005). Other species of *Cyclospora*, found in various reptiles and mammals (including primates), vary in size and appearance, but all, by definition for this genus, have oocysts that, when fully sporulated, contain two sporocysts, each with two internal sporozoites. The sporozoites are the structures that invade enterocytes.<sup>19–21</sup>

While *Cryptosporidium* spp. have caused large waterborne outbreaks, *C. cayetanensis* has been associated with smaller waterborne outbreaks, reportedly due to contaminated drinking water, notably in a medical dormitory in Chicago and among expatriates in a military detachment in Pokhara, Nepal.<sup>22,23</sup> In the Chicago case, an alternative epidemiologic hypothesis, that the outbreak may have been foodborne, has also been proposed.<sup>3</sup> The absence of reported widespread sources of water contamination may be due to the lack of animal reservoir hosts. Most investigated outbreaks of cyclosporiasis in the United States were foodborne rather

\* Outbreaks caused by *Cyclospora cayetanensis* (many U.S. states, several Canadian provinces, Germany, and other countries have experienced local outbreaks or been affected by widespread "outbreaks").

than waterborne and were associated with consumption of fresh produce, which either definitely was or could have been imported.<sup>3</sup> For example, outbreaks in May–June 1996 and April–May 1997, with a combined total of more than 2000 reported cases of cyclosporiasis in multiple U.S. states and Canadian provinces, were caused by consumption of fresh raspberries imported from Guatemala.<sup>3,14,15</sup> Foodborne outbreaks associated with other types of fresh produce (most notably, mesclun lettuce, basil, and snow-peas) have also occurred in the United States.<sup>3,14,24–27</sup>

Direct person-to-person transmission of *C. cayetanensis* is unlikely to occur because the organism is not immediately infectious when shed; the sporulation of oocysts, which renders them infectious, occurs only after excretion into the environment. Under laboratory conditions, sporulation requires at least 7 days<sup>7,8</sup>; the maximum rate at which sporulation can occur is unknown. This characteristic makes direct person-to-person transmission unlikely. Household clusters have been explained by common source (e.g., water) exposure.<sup>18</sup>

While outbreaks in the United States, associated with imported produce, have heightened awareness about cyclosporiasis, *Cyclospora* infections are more common and important in tropical and subtropical areas.<sup>28</sup> In addition, cases have been reported in travelers returning from or expatriates living in countries or regions such as Mexico, Haiti,<sup>29</sup> Nepal,<sup>9,10</sup> Southeast Asia,<sup>11,12</sup> Puerto Rico,<sup>30</sup> Indonesia,<sup>31</sup> Morocco, Pakistan, and India.<sup>32</sup>

Researchers in different countries note seasonality of infection with *C. cayetanensis*. However, the marked seasonality of *Cyclospora* infection, which varies by region, remains unexplained. In Nepal<sup>33</sup> and Guatemala,<sup>15,28</sup> most cases occur

during or near the rainy, hot spring or summer months. By contrast, in Indonesia, the peak season for cyclosporiasis occurs in the cooler, wetter months of October through May<sup>11</sup> and in Haiti, on the basis of preliminary data, probably in the cooler, drier months of January through March.<sup>34</sup> In a dry coastal area of Peru, infection occurs predominantly in the warmer months (albeit cooler than in Haiti) between December and June.<sup>35,36</sup>

Cyclosporiasis may be quite common in areas where it is endemic. During the 1992 rainy season in Nepal, Hoge and coworkers<sup>9</sup> found, in a clinic-based study, that 7% (18/254) of members of the U.S. embassy expatriate community were infected with what was then called a "coccidian-like body," now known as *C. cayetanensis*. A review of stools examined from both travelers to Nepal and foreign residents in two different clinics revealed *Cyclospora* spp. in 11% of 964 patients with diarrhea and in only 1% of 96 asymptomatic controls.<sup>9</sup> A cohort study in which 77 expatriates were followed in Nepal revealed that the annual risk for *Cyclospora* diarrhea was 32% in the first 2 years of residence in Nepal (second only to 42% for enterotoxigenic *Escherichia coli* and ahead of 16% for *Giardia lamblia* and *Shigella* spp. and 10% for *Campylobacter* spp.).<sup>37</sup>

In developing areas, studies of cyclosporiasis, like cryptosporidiosis, are primarily in children. In a 1994 study, Hoge and colleagues<sup>38</sup> found *C. cayetanensis* in the stool samples of 5% of 124 Nepalese children aged 6 to 60 months who sought treatment for diarrhea at an outpatient clinic in Kathmandu. *C. cayetanensis* was found in only 2% of 103 stools collected from children without diarrhea. No cases of cyclosporiasis were identified in 74 children less than 18 months of age who had diarrhea. In two prospective

studies of children living in slums in Lima, Peru, Ortega and colleagues<sup>7</sup> detected *Cyclospora* oocysts in stools of 18% of 147 children aged 1 to 2½ years during the period from January 1988 through July 1989 and in only 6% of 230 children aged 1 month to 1½ years from November 1989 through October 1991. However, in these studies, only 28% of the first group and 11% of the second group had diarrhea. In a community-based survey in Haiti in 1997–1998, in which stool specimens were collected from a cohort of mothers and children,<sup>34</sup> there were similar findings of high prevalence of asymptomatic infection in children. The prevalence of *C. cayetanensis* infection differed based on the month of collection of the stool samples and ranged from 5% to 16%. Of the 49 positive samples collected during the study, 41 (84%) were from children less than 10 years of age. Of those with positive stool samples, only 6% to 12% had diarrhea (different percentages reported for each month of collection). In a community-based study in Venezuela in 2001<sup>39</sup> that included persons from 2 months to 70 years of age, the highest prevalence of infection, 11.5% (7/61), was noted in persons aged 6 to 15 years, all of whom were asymptomatic. In contrast, in a case-control study of children hospitalized in Cuba, *C. cayetanensis* was found in 5/113 stool samples from patients with diarrhea and in 0/288 of hospitalized controls without diarrhea.<sup>40</sup>

In patients with AIDS, cyclosporiasis can be a common cause of prolonged diarrhea. In a 1990–1993 study in Haiti, Pape and associates<sup>41</sup> found *Cyclospora* spp., using the modified Kinyoun acid-fast method, in 11% of stool samples from (51/450) HIV-positive patients with diarrhea, making it the third most commonly identified parasitic pathogen after *Cryptosporidium* spp. and *I. belli*. Stools were not examined for *Campylobacter* spp., enterotoxigenic *E. coli*, or viral enteropathogens.

## DISEASE

If symptomatic, *Cyclospora* infection typically is associated with watery diarrhea, abdominal cramps or bloating, nausea, anorexia, and substantial weight loss. Some persons note vomiting and a low-grade fever.<sup>3,14,16</sup> Many experience a prodromal flu-like illness and profound, persistent fatigue, long after the gastrointestinal symptoms have resolved.<sup>3,42</sup> If the infection is not treated, the symptoms can persist for weeks to months and can remit and relapse.<sup>3</sup>

In patients with AIDS, cyclosporiasis, like cryptosporidiosis, can be associated with protracted, fulminant diarrheal illness and weight loss. Presumed acalculous cholecystitis associated with *C. cayetanensis* infection has been reported in patients with AIDS.<sup>43–45</sup> Other than possible associations with Reiter's syndrome or Guillain-Barré syndrome, no other extraintestinal disease has been reported.

*C. cayetanensis* infection causes histopathologic changes in the small bowel similar to those seen in patients with cryptosporidiosis. Villous blunting, crypt hyperplasia, edema, hyperemia, and an inflammatory infiltrate with epithelial disarray, especially prominent at the villous tips, is described.<sup>46</sup> In contrast to *Cryptosporidium* spp., which reside in an extra-cytoplasmic parasitophorous vacuole at the luminal surface of the enterocyte, *Cyclospora* is found in an intracytoplasmic parasitophorous vacuole in the apical supranuclear region of the enterocyte.<sup>3,7,16</sup> Cyclosporiasis is often associated with

evidence of malabsorption, such as an abnormal D-xylose test and abnormal lactulose:mannitol permeability ratio.<sup>46</sup>

## DIAGNOSIS

Cyclosporiasis should be included in the differential diagnosis for persistent diarrheal illness. Testing for *Cyclospora* spp. should be specifically requested because it is not routinely done by most laboratories, even when testing for ova and parasites is requested. Symptoms include prolonged watery diarrhea, abdominal cramps, low-grade fever, and pronounced fatigue. Currently, no abnormalities found on routine blood tests are specifically associated with cyclosporiasis.

Once found on acid-fast staining of fecal specimens, *C. cayetanensis*, which measures 8 to 10 µm, must be distinguished from *Cryptosporidium parvum* and *hominis*, which also are acid-fast but measure only 4 to 5 µm. Since infected persons may excrete low numbers of oocysts (even with severe diarrhea), concentration of samples may be necessary and multiple samples may need to be examined.<sup>3</sup>

Despite these challenges, several additional features of *C. cayetanensis* oocysts are helpful in identification. Ultraviolet fluorescence microscopy is useful for rapid screening of stool specimens for *C. cayetanensis* because it, in contrast to *Cryptosporidium* spp., is autofluorescent. This is one reason *C. cayetanensis* was initially confused with cyanobacteria.<sup>5,12</sup> In contrast to oocysts of *Cryptosporidium* spp., which are excreted in their sporulated, infective form with four sporozoites visible in fecal oocysts, *C. cayetanensis* oocysts are shed unsporulated in fecal specimens. They have an undifferentiated cytoplasm with multiple refractile globules rather than distinct sporozoites.<sup>3</sup>

Cyclosporiasis can also be diagnosed by histopathology or electron microscopy of jejunal biopsy specimens or aspirates. No serologic tests for antibodies to the parasite are commercially available. Sturbaum and coworkers<sup>47</sup> and others have described molecular methods including polymerase chain reaction (PCR) for detection of *Cyclospora* in stool or wastewater. Others have used PCR methods to detect *Cyclospora* in produce<sup>48</sup> and in stool specimens from returning travelers.<sup>49</sup>

## TREATMENT

The treatment of choice for cyclosporiasis is oral administration of one double-strength tablet of trimethoprim-sulfamethoxazole (TMP-SMX) twice daily for a week. This treatment eliminated the organism and relieved symptoms in a placebo-controlled trial in immunocompetent adults.<sup>42</sup> This treatment also is effective in patients with AIDS, but maintenance therapy with a single dose of one double-strength tablet of TMP-SMX three times a week may be indicated to prevent relapse.<sup>41</sup>

To assess an alternative treatment in patients who cannot tolerate sulfa-based therapies, a clinical trial in Haiti of HIV-infected patients with cyclosporiasis compared patients treated for 7 days with either TMP-SMX (one double-strength tablet four times a day) or ciprofloxacin (500 mg twice a day). The patients' reports of symptoms and a stool sample were collected on day 8. The stool samples were screened by wet-mount for coccidial oocysts and, if positive, were further examined with the modified Kinyoun acid-fast method for

morphologic identification. By day 8, all patients (9/9) treated with TMP-SMX had become asymptomatic and no longer had *C. cayetanensis* oocysts detectable in their stool samples; among those treated with ciprofloxacin, 90% (10/11) had become asymptomatic but only 64% (7/11) had negative stool specimens.<sup>50</sup> The results of this small clinical trial suggest that ciprofloxacin might be an alternative drug for persons who cannot tolerate sulfa-based therapies. However, the results should be confirmed in other patient populations because anecdotal experience among immunocompetent patients suggests that ciprofloxacin is not as effective as TMP-SMX for cyclosporiasis.<sup>3</sup>

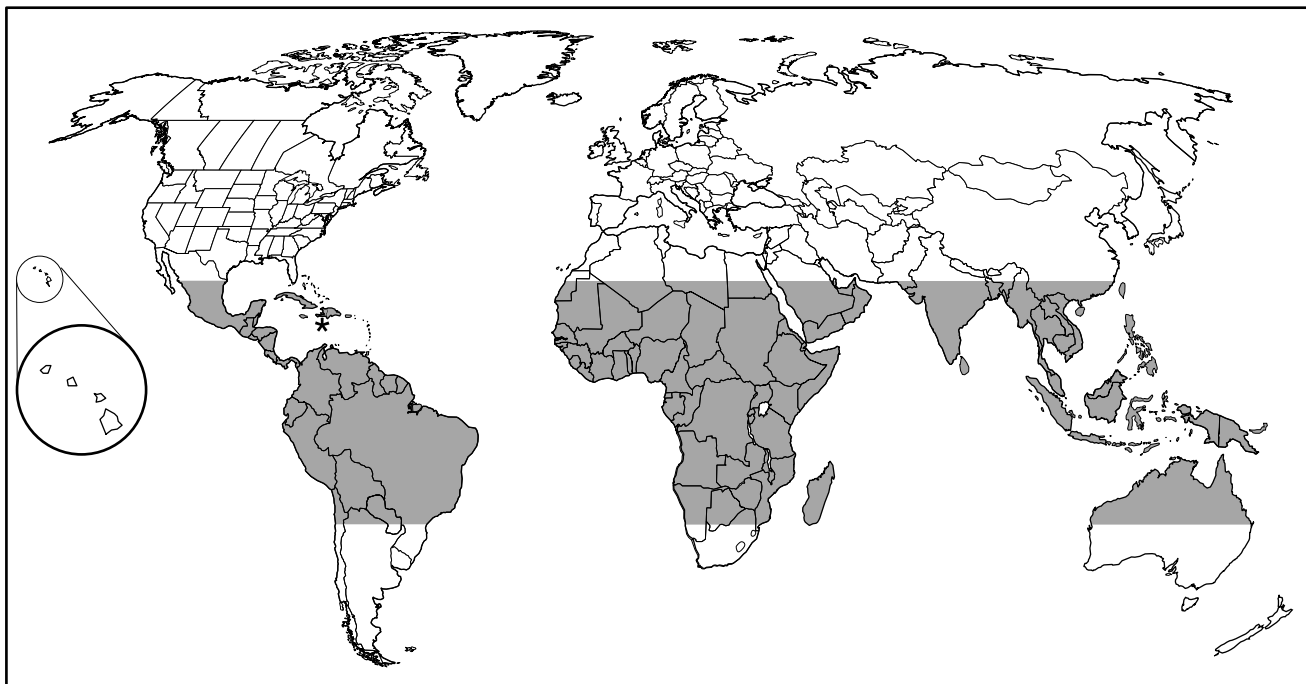

## PREVENTION AND CONTROL

Extensive epidemiologic investigations have identified food items associated with outbreaks in the United States. For example, analyses of frozen implicated leftover food following an outbreak associated with a wedding reception in Philadelphia in 2000 led investigators to perform PCR analysis of raspberry-filled wedding cake. This testing identified *C. cayetanensis* DNA and ultimately identified Guatemala as the source of the implicated raspberries.<sup>27</sup>

Strategies to prevent outbreaks of cyclosporiasis caused by imported food items that are eaten raw (uncooked) could include identification and implementation of measures to prevent contamination of the food in the source country, identification and avoidance of contaminated food items, and the capability to decontaminate the food item. Since *C. cayetanensis*, like *Cryptosporidium* spp., is highly resistant to

chlorine, chlorinating agricultural or irrigation water is unlikely to help prevent transmission, and thorough washing of fresh produce has not been demonstrated to eliminate the risk of cyclosporiasis.<sup>3</sup> Although studies in Norway failed to identify *Cyclospora* oocysts on imported produce (despite finding *Giardia* cysts and *Cryptosporidium* oocysts),<sup>51</sup> *Cyclospora* DNA and an oocyst were found in the implicated leftover basil-containing food item in the investigation of an outbreak in 1999 in Missouri<sup>25</sup> and in produce (even after washing) purchased in a Peruvian market.<sup>52</sup> One group of researchers hypothesized that application of pesticides might prevent sporulation and thus infectivity of *C. cayetanensis*. They evaluated in vitro application of commercially available pesticides, but the pesticides failed to prevent sporulation of *Cyclospora* oocysts.<sup>53</sup> Regarding prospective identification of contaminated products, PCR-based assays sensitive enough to detect low-level contamination of food and water sufficient to cause infection are in development.<sup>54</sup> Finally, a possible decontamination strategy is gamma irradiation of produce. However, not all produce can withstand irradiation. For example, lettuce may wilt following irradiation.<sup>55</sup>

Preventing cyclosporiasis in tropical and subtropical areas should also be a priority. However, the many questions that remain relative to both the *C. cayetanensis* life cycle outside the human host and the pathogenesis of infection within the host pose challenges to developing rational environmental or immunologic prevention strategies. In addition, infected humans are the only source of oocysts for study, and no animal or in vitro model is currently available to help researchers evaluate viability or infectivity.<sup>15,20</sup>

\* *Isospora belli* highly endemic in Haiti among persons with AIDS

## ■ Isospora

### AGENT AND EPIDEMIOLOGY

*I. belli* was first identified in U.S. troops abroad during World War I, and this association gave the species its name.<sup>56</sup> However, *I. belli* was not studied further until 1970 when Brandborg and colleagues<sup>57</sup> identified it in tissue sections from patients with malabsorptive enteritis. Since then it has been recognized primarily in residents of and travelers to developing areas, especially those with AIDS.

The oblong oocyst of *I. belli* is a larger (10–20 × 20–30 μm) and more complex structure than the oocyst of *C. cayetanensis*. It contains two sporocysts with four sporozoites in each. The asexual phase of the life cycle (from ingested oocyst through sporozoite release and meront formation) is similar to that of *C. cayetanensis*. However, *I. belli* does not form identifiable type 2 meronts; rather, the merozoites presumably can develop either into trophozoites or gametocytes. Like the oocysts of *C. cayetanensis*, the oocysts of *I. belli* are not immediately infectious when excreted in stool. Under laboratory conditions, oocysts exposed to oxygen at temperatures slightly below 37°C sporulate in 24 to 48 hours. The duration of oocyst passage has been reported to last from 21 to 120 days.<sup>58,59</sup>

Humans are the only known hosts for *I. belli*, although other *Isospora* spp. are found throughout the animal kingdom. *I. belli* is distributed worldwide, with highest prevalence in tropical and subtropical climates. In contrast to *Cryptosporidium* spp., *I. belli* is rarely reported as a cause of diarrhea in immunocompetent children living in developing countries. In a 2-year period, the stools of 824 infants in Haiti were examined with a modified Ziehl-Nielsen method for the presence of coccidian parasites. None of the stools contained *I. belli* oocysts, whereas 17% of the stools contained *Cryptosporidium* spp. oocysts.<sup>60</sup> Analysis of a community-based cohort study of children aged from 3 weeks to 2 years in Guinea that was conducted from 1996 to 1998 did suggest an association between diarrhea and *I. belli* (OR for diarrhea 3.55 [95% CI: 1.15–11.0]) although the incidence was low (11 cases/168.7 child-year at risk).<sup>61</sup> Outside the tropics and subtropics, isosporiasis is usually found only in patients with a history of travel to these areas.<sup>62</sup> In the tropics, immunosuppressed patients are particularly at risk for isosporiasis. In a 1985 study of HIV-infected patients with diarrhea in Haiti, *I. belli* was found in 15% (20/131) of stool specimens. *Cryptosporidium* spp. was the only parasitic pathogen found more frequently in that study.<sup>63</sup>

Acquisition of isosporiasis is thought to be due to ingestion of food or water contaminated with mature oocysts from human feces. *I. belli* oocysts are not immediately infectious, so person-to-person transmission is considered rare. In the study mentioned previously that evaluated patients in Haiti with AIDS and isosporiasis, *I. belli* oocysts were detected in none of 170 healthy household or heterosexual contacts of the patients by acid-fast stains of concentrated stool specimens.<sup>63</sup>

### DISEASE

Isosporiasis generally produces a self-limited diarrheal illness in otherwise healthy persons. The symptoms can resemble cyclosporiasis or cryptosporidiosis, with watery diarrhea

and abdominal pain usually lasting less than 1 month. However, chronic isosporiasis, with malabsorption and weight loss, has been reported in immunocompetent patients. The disease can resemble celiac sprue.<sup>57</sup> Two deaths due to chronic isosporiasis in otherwise healthy children under age 2 years have been reported.<sup>58</sup>

In immunocompromised patients, isosporiasis may be prolonged and more severe. In the 1985 Haitian case series described previously, the median duration of diarrhea was 5.8 months and the diarrhea was associated with diffuse abdominal cramps and nausea.<sup>63</sup> Dissemination of infection to mesenteric and tracheobronchial lymph nodes has been reported in one patient, and dissemination to lymph nodes, liver, and spleen in another.<sup>64</sup> Acalculous cholecystitis in patients with AIDS and *I. belli* infection also has been reported.<sup>65,66</sup>

When observed histopathologically, *I. belli* is found invading beyond the epithelium into the lamina propria.<sup>57</sup> Although the histopathologic changes are similar to those described in cyclosporiasis, infiltration of large numbers of eosinophils into the lamina propria and dilation of the lymphatics reportedly are more common with *I. belli* infection.<sup>58</sup>

### DIAGNOSIS

Isosporiasis should be considered in residents of or travelers to tropical areas who experience persistent diarrhea, abdominal cramps, steatorrhea, weight loss, and sometimes low-grade fever. As with cryptosporidiosis and cyclosporiasis, there are no characteristic physical findings or abnormalities on routine laboratory analyses. However, peripheral eosinophilia is sometimes noted and may explain the observation of Charcot-Leyden crystals in the stool specimens of some patients with isosporiasis.<sup>58,67</sup> Fecal leukocytes usually are not seen.<sup>63</sup>

*Isospora* infection is diagnosed by seeing the organism in stool. The oocysts stain bright red with modified acid-fast techniques and may also be autofluorescent, and they are clearly distinguishable from *Cyclospora* or *Cryptosporidium*. *Isospora* oocysts are much larger and elliptical (10–20 × 20–30 μm). Other techniques, including lactophenol cotton blue staining, the auramine-rhodamine technique, Giemsa staining, and the heated safranin-methylene blue technique have also been used to identify *I. belli* oocysts in stool samples.<sup>58,68</sup> Shedding of oocysts may be intermittent. In a case series of 34 patients with AIDS and isosporiasis, diagnosis of *I. belli* infection in seven patients required examination of three stool specimens for each patient.<sup>69</sup> In some cases, the organism has been visualized by light microscopic examination of a small bowel biopsy specimen, a duodenal aspirate, or a mucus specimen collected by the duodenal string test.<sup>57,58</sup> No serologic tests for *Isospora* are commercially available. Muller and associates<sup>70</sup> reported the successful identification of *I. belli* DNA by a PCR assay of small bowel tissue. However, PCR has not been validated for the evaluation of stool specimens for *I. belli* and is not available commercially.

### TREATMENT AND PROGNOSIS

Isosporiasis can be treated successfully in patients with or without AIDS. The regimen of choice for adults in both

groups is one double-strength tablet of TMP-SMX administered orally two to four times daily for 10 days. (The higher dose, and longer treatment, may be needed for immunosuppressed patients.)<sup>71</sup> In a study that used this regimen for patients with AIDS and isosporiasis in Haiti in 1988, this treatment resulted in complete symptomatic relief as well as parasitologic remission for all patients. In the same study, the efficacy of various prophylactic regimens was evaluated. Relapses were common in the group that received placebo therapy for secondary prophylaxis after the initial treatment (50% within 1.6 months of completing the initial treatment). Maintenance therapy with one of two regimens—one double-strength TMP-SMX tablet three times a week or one Fansidar tablet (pyrimethamine 25 mg plus sulfadoxine 500 mg) once a week—prevented all symptomatic relapses. One asymptomatic patient who was receiving TMP-SMX prophylaxis had *I. belli* identified in a routine follow-up stool sample.<sup>69</sup>

For treatment of patients who are intolerant of sulfonamide-containing medications, an alternative regimen is oral pyrimethamine 50 to 75 mg/day in individual doses (+ leucovorin 10 to 25 mg/day).<sup>71,72</sup> Other drugs reported to be effective are roxithromycin 2.5 mg/kg every 12 hours for 15 days and diclazuril.<sup>73,74</sup> The therapeutic efficacy of these drugs needs to be confirmed, but these regimens are also alternatives for patients intolerant of drugs containing sulfonamides. Prevention of relapses in immunocompromised patients who are intolerant of sulfa-containing drugs can be achieved with pyrimethamine alone at 25 mg/day.<sup>69</sup>

## ■ Sarcocystis

### AGENT

*Sarcocystis* spp. belong to the family Sarcocystidae. Their life cycle differs from the coccidia discussed previously in that they

require two separate hosts for completion: a definitive host (in which the sexual stage develops, usually a carnivorous predator) and an intermediate host (often herbivorous prey). The cycle in the intermediate host begins with ingestion of infectious sporocysts or oocysts. These excyst in the small intestine to release sporozoites that penetrate the mucosa and develop into schizonts in the vascular endothelium. The schizonts release merozoites that enter the circulation and lodge in skeletal or cardiac muscle to form sarcocysts. When muscle that contains sarcocysts is ingested by the definitive host, the cysts rupture to release zoites (also called bradyzoites or cystozoites) that invade the intestinal epithelium and differentiate into male or female gametocytes. After fertilization, which occurs within 24 hours, zygotes undergo encystation and sporulation, and oocysts (with two sporocysts, each with four sporozoites) are excreted in the stool, and the cycle continues.

Humans can be intermediate or definitive hosts for *Sarcocystis* species. If they are intermediate hosts, the infections are considered zoonotic. However, humans are the definitive hosts for *Sarcocystis suihominis* and *Sarcocystis bovi hominis* (or *Sarcocystis hominis*). The intermediate hosts are pigs and cows, respectively. Persons who ingest tissue sarcocysts of these species may develop gastrointestinal symptoms attributed to infection of the intestinal mucosa. Humans are also thought to ingest *Sarcocystis* spp. sporocysts directly, which can lead to the development of intramuscular cysts.

### EPIDEMIOLOGY

Various *Sarcocystis* species are identified throughout the world, with cases of muscle sarcocystosis reported in people in Southeast Asia, India, Africa, Europe, and North and South America (including the United States). Infection may be quite common in some areas. Prevalence rates of 10% and 20% to 23% were observed in adults in rural areas

■ Intestinal *Sarcocystis* spp.

# Sarcocystis hominis

of Laos and Tibet, respectively. Most of these infections were asymptomatic.<sup>75,76</sup> Infection is thought to be due to consumption of undercooked beef or pork. In one case series, infections were associated with consumption of raw beef.<sup>77</sup>

## DISEASE

Disseminated sarcocystosis is thought to result from the presence of cysts within muscle. However, sarcocysts have been found in biopsy specimens from asymptomatic persons as well as in specimens from patients with myalgias. Other patients with cysts in biopsy specimens have been found to have eosinophilia, polyarteritis nodosa, or, in one reported case, cardiomyopathy.<sup>78</sup> Whether the sarcocysts per se cause such manifestations has been difficult to establish.

Intestinal sarcocystosis can also result in several clinical presentations. As noted previously, most infections are

asymptomatic. However, there are reports from Thailand of segmental eosinophilic or necrotizing enteritis requiring resection.<sup>79</sup> One volunteer who ingested 60 g of beef experimentally infected with *S. hominis* developed anemia, abdominal pain, diarrhea, fatigue, and dizziness 3 days later and shed oocysts for 42 days beginning on day 8.<sup>79</sup>

## DIAGNOSIS AND TREATMENT

Intestinal sarcocystosis can be diagnosed by observation of sporulated sporocysts or oocysts in stool. The cysts resemble *Isospora* oocysts; they are acid-fast and contain two sporocysts. However, the thin-walled oocysts usually rupture in the bowel, releasing the sporocysts, which are not seen. Oocysts measure  $15.5 \times 20 \mu\text{m}$  and sporocysts  $12 \times 6 \mu\text{m}$ . Infection can also be diagnosed by observation of trophozoites or bradyzoites in biopsy tissue, although the organism

can be mistaken for *Toxoplasma gondii* (in muscle) or *I. belli* (in the intestine).<sup>56,77,78</sup> Sulfadiazine, tinidazole, and acetylsalicylic acid have been reported to be active against intestinal *Sarcocystis* infection.<sup>76</sup> In cases of severe enteritis, segmental resection may be necessary. No clinical trials have been conducted to guide treatment of tissue sarcocystosis.

## PREVENTION AND CONTROL

Presumably, thorough cooking of meat, especially of beef and pork, would prevent intestinal sarcocystosis. The internal temperatures required to guarantee the safety of meat are unknown, as is the effectiveness of alternative preparation techniques (e.g., curing, smoking). Regardless, raw meat should not be eaten because of the risk for infection with other known pathogens, such as cestodes, *Trichinella* spp., *T. gondii*, and enterohemorrhagic *E. coli*.

Treating animals raised for human consumption to reduce the incidence of sarcocystosis is another possible prevention strategy. However, this has proved difficult. In a survey of beef cattle in New Zealand, all the cattle tested were infected with a *Sarcocystis* species. In 80% of the cattle, the organism resembled *S. hominis*.<sup>80</sup> However, the human pathogen *S. hominis* cannot be distinguished by light microscopy from the related species *Sarcocystis hirsuta*. Therefore, the prevalence of *S. hominis* infection is difficult to determine.<sup>81</sup>

NICHOLAS J. WHITE

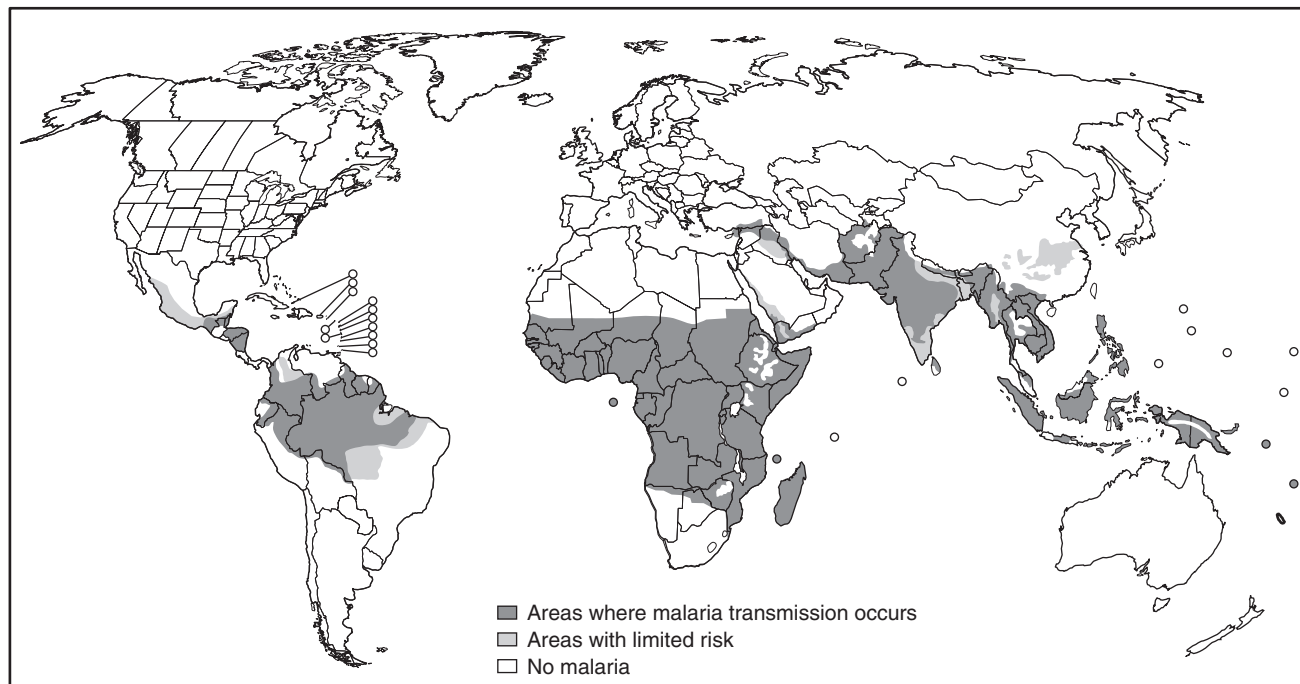

## INTRODUCTION

Malaria is an acute systemic illness caused by infection with *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, or *Plasmodium ovale*, all of which are transmitted to humans by female *Anopheles* species mosquitoes. There are an estimated 300 to 800 million clinical cases of malaria and 1 to 3 million deaths due to malaria annually in the tropics and subtropics.<sup>1</sup> The majority of the infections and deaths are caused by *P. falciparum* infection of children in sub-Saharan Africa. In fact, *P. falciparum* is responsible for more deaths in children less than 5 years of age than any other single infectious agent. In Africa, malaria is estimated to result in a minimum economic loss of \$12 billion annually.<sup>2</sup>

All symptoms, signs, and pathologic features of the disease are caused by the asexual erythrocytic stage of the parasite's life cycle (see later discussion). This stage involves invasion of normal erythrocytes by parasites, replication of the parasites in the erythrocytes over 2 to 3 days (Table 90-1), rupture of the erythrocytes, and reinvasion of normal erythrocytes. This exponential parasite replication in the bloodstream can increase parasite density by 5- to 30-fold every 2 to 3 days.

Malaria caused by any of the four *Plasmodium* species is characterized by fever, chills, diaphoresis, malaise, headache, and other systemic symptoms and signs indistinguishable from illnesses caused by many viral and bacterial pathogens. *P. falciparum* is unique among the human malaria-causing parasites in that essentially all malaria deaths are caused by *P. falciparum*. This is in large part due to two unique features of the parasite. Only *P. falciparum* invades erythrocytes of all ages (see Table 90-1), meaning that the percentage of erythrocytes infected can reach levels as high as 80% ( $>2 \times 10^6$  parasites/ $\mu\text{L}$  blood depending on the degree of anemia), thereby increasing the chance that the infection will cause serious disease. Only *P. falciparum* secretes proteins that form knobs on the surface of the infected erythrocyte that bind to endothelial cells in the microcirculation of the brain, kidneys, intestines, and other organs during the second half of the parasite's 43- to 48-hour development cycle in erythrocytes. These adherent infected erythrocytes are responsible for microcirculatory obstruction, leading to decreased blood flow and oxygen delivery, and local inflammatory responses critical to the pathogenesis of the severe manifestations of disease that make *P. falciparum* potentially so lethal.

MALARIA, 2003

Areas of the world where malaria is transmitted, with differentiation between high and minimal risk areas. (Courtesy of Dr. M. Parise: Health Information for International Travel. Atlanta, Centers for Disease Control and Prevention, 2005–2006, in press.)

**Table 90-1** Differences among *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*

Characteristic	<i>P. falciparum</i>	<i>P. vivax</i>	<i>P. ovale</i>	<i>P. malariae</i>
Life cycle				
Maximum time sporozoites circulate in bloodstream (min)	30	60	?	?
Primary liver stage (day)	5.5–7	6–8	9	14–16
Delayed primary liver stage (mo)	9*	10.5	?	?
Relapse from secondary liver stage (hypnozoites)	–	+	+	–
Length of secondary liver stage (mo)	–	1–36	?	–
Liver stage (No. of merozoites/schizont)	30,000	10,000	15,000	2000
Liver stage (diameter, $\mu\text{m}$ )	55	50	45	40
Erythrocyte preference	Young, but all invaded	Reticulocytes or RBCs up to 14 days old	Reticulocytes	Old
Asexual erythrocytic stage (hr)	43–52	48	48	72
Prepatent period (average No. of days)	11	12.2	12.0	32.7†
Incubation period (average No. of days)	13.1	13.4	14.1	34.7
Asexual erythrocytic stage (cytoadherence)	+	–	–	–
Asexual erythrocytic stage (persistence if inadequately or not treated, yr)	1–2	1.5–5	? same as Pv	3–50
Mosquito cycle = sporogonic cycle (gametes to salivary gland sporozoites)	9–13	8–10	12–14	14–16
Morphologic findings in blood films‡				
Rings				
Shape	Fine, oval, circular	Irregular, large, thick	Regular, dense	Dense, thick
Appliqué (squeezed to edge of cell)	Occurs	–	–	–
Chromatin dots	1–2	1	1	1
Parasite density >2%	Frequent	Rare	Rare	Rare
Trophozoites				
Band forms	–	–	–	+
Schizonts				
Found in peripheral blood	Rare	+	+	+
Pigment	Dark brown-black	Orange-brown	Brown	Black
No. of merozoites	8–32	12–18	8–14	8–10
Gametocytes				
Shape	Banana-shaped	Round or oval	Large, round	Large, oval
Male	Light blue	Pale blue (round)	Dense, blue	Pale blue
Female	Darker blue	Dark blue (oval)	Dense, blue	Dense, blue
Pigment granules	Few blue-black	Few orange	Brown	Large, black
Erythrocyte changes				
Enlarged	–	+	+	–
Pale cytoplasm	+	–	–	–
Oval with tufted edges	–	–	Frequent	–
Crenated	Occurs	–	–	–
Red dots in cytoplasm	Mauer's clefts	Schuffner's dots	James' dots	–

\*In *P. falciparum*, delayed appearance of blood-stage infection has been documented in travelers, but it is unclear whether this results from delayed emergence from the liver or from delayed development in erythrocytes.

†Data for *P. malariae* are derived from experimental challenges reported in Boyd MF (ed): *Malaria: A Comprehensive Survey of All Aspects of This Group of Diseases from a Global Standpoint*. Philadelphia/London, WB Saunders, 1949.

‡Preparation of blood films: Thin and thick blood films are routinely prepared on the same slide. Two drops of blood are placed at one end of a clean glass slide. The thin film is made by placing the edge of a second slide into the edge of the more medial drop at an approximately 45-degree angle and spreading the blood across the entire slide. The thick film is made by placing the corner of a second slide into the drop and circularly spreading the blood to approximately the size of a U.S. penny. The thin-film portion is fixed with methanol, preserving the erythrocytes. The thick-film portion is not fixed, and the erythrocytes are lysed when the slide is stained.

Malaria has had an enormous impact on human health for millennia. Hippocrates described the clinical presentation and complications of malaria in the 5th century BCE. Nearly half a millennium later, Celsus (25 BCE to 54 CE) provided an in-depth description of the distinction between the clinical manifestations of disease caused by *P. falciparum*, *P. vivax*, and *P. malariae*.<sup>3</sup> In the 1630s it was discovered that the bark of

the cinchona tree from Peru could treat the disease. “Peruvian” or “Jesuit’s” bark was imported to Europe and became widely used in treatment,<sup>4,5</sup> and Morton and Sydenham in England and Torti in Italy distinguished between the fevers that responded to the bark and those that did not.<sup>3</sup> In England, the responsive fevers were called “agues.” In the 18th century they received the Italian name, malaria (*mal aria* = bad air) because

# Malaria

it was believed that the disease was transmitted through the foul air of swampy areas. In 1820 Pelletier and Caventou in France determined that quinine was the active component of the bark, and the era of modern chemotherapy was initiated despite complete ignorance regarding the cause of the disease.

In 1880 Alphonse Laveran, a French military physician, working in Algeria, made the first description of malaria parasites in the blood of patients.<sup>6</sup> Transmission of malaria by *Anopheles* mosquitoes was discovered in 1897 by Ronald Ross, a British military physician, working in India.<sup>7</sup> Ross found a malaria parasite in a mosquito that previously fed on a patient with parasites in his bloodstream. The complex life cycle in humans was elucidated in 1898–1899 by Italian scientists Amico Bignami, Giuseppe Bastianelli, and Battista Grassi.<sup>3</sup> Laveran (1907) and Ross (1902) were awarded Nobel Prizes for their discoveries.

The discovery of the life cycle led to initiation of control efforts aimed at reducing mosquito populations to reduce transmission of the disease. In some places, such as Panama during the building of the canal, these efforts were highly successful. However, malaria continued to be a problem throughout the world. During World War II, U.S. forces lost 12 million man-days to malaria,<sup>8</sup> and major efforts were initiated to develop better methods of prevention and treatment. By the end of the War, DDT, which had been demonstrated to be an insecticide by Mueller in Switzerland in 1939, and chloroquine, a 4-aminoquinolone discovered in Germany in the 1930s, had been shown by the U.S. military to be highly effective against the mosquitoes and parasites responsible for malaria. These new tools provided the foundation for major efforts that led to the elimination of malaria in the United States and Europe and to dramatic reduction of transmission

of malaria in a number of countries in South and Central America, North Africa, and Asia, but with little impact in most countries of sub-Saharan Africa.<sup>9</sup>

In 2005 the impact of malaria in many parts of the world is similar to or greater than it was 50 years ago. *P. falciparum* has become resistant to a range of drugs, the mosquitoes have become resistant to many insecticides, and the health services infrastructure required to deliver effective malaria control measures sustainably has deteriorated or never been established. In recent years several promising new malaria control interventions have been field-tested that could, if deployed to high levels of population coverage, dramatically reduce malaria burden, especially in sub-Saharan Africa. They include interdicting contact between humans and infected mosquitoes by use of insecticide-impregnated bed nets, residual insecticide spraying, and reduction of breeding places and reducing the effects of the disease by early diagnosis and treatment and by intermittent therapy, independent of evidence of infection in pregnant women and infants. The global community has committed to reducing the health and economic impact of malaria, and funding for malaria control is being made available by international and national entities. There are substantial efforts aimed at developing vaccines, but they are years away from deployment.

## AGENT

Malaria is caused by protozoa of the genus *Plasmodium*, family Plasmodiidae, suborder Haemosporidiidea, order Coccidiida. There are more than 120 *Plasmodium* species that infect mammals, birds, and reptiles. Only four species are known to consistently infect humans: *P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*. *P. knowlesi*, a simian malaria parasite, has intermittently been reported to cause human disease.<sup>10</sup>

Understanding malaria is dependent on understanding the complex life cycle of the parasite in its definitive host in which sexual development occurs—the mosquito—and its intermediate host—the human (see life cycle). The life cycle of *P. falciparum* is described in the following section, the unique terminology is described in Box 90-1, and the differences among *P. falciparum* and its life cycle and that of *P. malariae*, *P. vivax*, and *P. ovale* are described in Table 90-1 and in the following sections.

## Life Cycle of *P. falciparum*

When an infected female *Anopheles* spp mosquito feeds on a human (Fig. 90-1A), she is thought to inoculate an average of 5 to 10 and as many as 100 uninucleated sporozoites (approximately  $1 \times 7 \mu\text{m}$ ) into the tissues or directly into the bloodstream<sup>11</sup> (Fig. 90-1B). The sporozoites rapidly pass through the bloodstream to the liver (probably within 2 minutes, but no more than 30 minutes).<sup>12</sup> In the sinusoids they penetrate and pass through Kupffer cells<sup>13</sup> and invade hepatocytes through a specific receptor-ligand interaction. The primary receptor is thought to be sulfated heparan glycans on the hepatocyte surface, and the parasite ligands include the thrombospondin domains of at least two sporozoite proteins—the circumsporozoite protein<sup>14</sup> and a protein known both as the thrombospondin-related anonymous protein (TRAP)<sup>15</sup> and as sporozoite surface protein 2.<sup>16</sup> The sporozoites

## Box 90-1 Terminology of Malariologists

**Prepatent period:** The time from inoculation of sporozoites until asexual erythrocytic stage parasites are demonstrated in the bloodstream.

**Incubation period:** The time from inoculation of sporozoites until the individual first manifests symptoms or signs of malaria.

**Recurrence:** Repeat infection causing malaria that is result of a relapse, recrudescence, or reinfection.

- **Relapse:** A recurrent infection caused by full development of hypnozoites from the liver. Relapses are thought to occur only with *P. vivax* or *P. ovale* infections.

- **Recrudescence:** A recurrent infection caused by full development of a blood-stage infection in which parasitaemia declined below the level of detection and then rose above the level of detection. Recrudescence occurs most commonly after inadequate treatment as a result of drug resistance, unusual pharmacokinetics, or incomplete dosage. It can also occur in immunocompromised individuals whose immune systems have been controlling an extremely low grade asexual erythrocytic stage infection for years, especially when the parasite is *P. malariae*.

- **Reinfection:** A recurrent infection caused by a new exposure to infected *Anopheles* mosquitoes.

**Classification of endemicity:** This classification scheme has been used since the 1950s, but many malariologists do not currently find it useful because of the poor correlation between the number of 2- to 9-year-olds with palpable spleens and positive blood films and the intensity of malaria transmission in settings where people are fed on by more than 20 infected mosquitoes per year.

Type

Palpable Spleen (Spleen Rates)  
Positive Blood Film

Holoendemic

>75% in 2- to 9-year olds, and low in adults  
>75% in 2- to 9-year olds

Hyperendemic

>50% in 2- to 9-year olds, and >25% in adults  
>50% in 2- to 9-year olds

Mesoendemic

11%-50% in 2- to 9-year olds  
11%-50% in 2- to 9-year olds

Hypoendemic

<11% in 2- to 9-year olds  
<11% in 2- to 9-year olds

may invade several hepatocytes before finding the correct hepatocyte in which to develop.<sup>17</sup> In the hepatocyte, host cell material is used to form a “parasitophorous” vacuole that separates the parasite from the cytoplasm of the hepatocytes. During a minimum of 5.5 days, the uninucleated *P. falciparum* sporozoite develops to a mature liver-stage schizont with an average of 30,000 and range of 10,000 to 40,000 uninucleated merozoites (see Fig. 90-1C and Table 90-1).

The mature liver-stage schizont ruptures, releasing the thousands of merozoites that are about  $1.5 \mu\text{m}$  in diameter, each of which can invade a normal erythrocyte (Fig. 90-1D). There are a number of steps in this process (Fig. 90-1E), but there is unquestionably a specific interaction between receptors on the erythrocyte membrane and ligands on the merozoite surface. One of these receptor-ligand interactions is

**FIGURE 90-1** Vector and parasites at different stages of the life cycle. *A*, *Anopheles stephensi* mosquito feeding in characteristic posture. *B*, *P. falciparum* sporozoites in a crush preparation of a salivary gland (Giemsa stain). *C*, Mature liver-stage schizont of *P. falciparum* with thousands of merozoites (hematoxylin and eosin stain). *D*, *P. falciparum* merozoite attaching to uninfected erythrocyte prior to invasion (scanning electron micrograph). *E*, Schematic of the process of a *P. falciparum* merozoite invading an erythrocyte. *F*, *P. falciparum* merozoites rupturing from an infected erythrocyte. Note “knobs” on the surface of the infected, unruptured erythrocyte above the rupturing erythrocyte (scanning electron micrograph).

Bannister, Wellcome Trust International Health Image Collection.

between sialic acids and peptides on erythrocyte glycophorin A and the 175-kd erythrocyte-binding antigen (PfEBA175) on the merozoite.<sup>18</sup> In the erythrocyte, the invading merozoite develops within a parasitophorous vacuole composed of host cell material. During the next 43 to 48 hours, the uninucleated merozoite develops to maturity within the parasitophorous vacuole. First, it becomes a trophozoite and begins to secrete proteins that pass through the parasite membrane and the parasitophorous vacuole membrane and form knobs in the erythrocyte membrane (Fig. 90-1F). The proteins in the knobs, especially one called *P. falciparum* erythrocyte membrane protein 1 (PfEMP1),<sup>19–21</sup> bind to receptors on endothelial cells in capillaries and postcapillary venules, sequestering the infected erythrocyte in the microcirculation for the last 24 to 34 hours of its development cycle, when it changes from an immature schizont to a mature asexual erythrocytic stage schizont with an average of 16 uninucleated merozoites. It is thought that the parasite has developed this mechanism to prevent the increasingly rigid infected erythrocyte from being removed from the circulation when it passes through the spleen. When fully mature, the infected erythrocyte ruptures, releasing the merozoites (see Fig. 90-1F), which then invade normal erythrocytes, initiating the cycle of intra-erythrocytic stage development, rupture, and reinvasion that leads to a 10- to 20-fold increase in the numbers of *P. falciparum* parasites in the bloodstream every 43 to 48 hours and to all the clinical manifestations and pathology of malaria.

Alternatively, the erythrocytic stage parasites can develop to sexual stage parasites called gametocytes (Fig. 90-1G). In the gut of the mosquito, the gametocytes escape from the erythrocytes and form gametes. The male gamete fuses with the female, forming a zygote. At about 5 hours after blood-feeding, the zygote undergoes two-step meiosis. By 18 to 24 hours, the zygote has transformed into an ookinete.
